The problem of mental disease has assumed such proportions in this Commonwealth—there were over 21,000 persons treated in our state hospitals last year; new cases are being admitted at a rate of over 3000 a year; over one-quarter of the total expense of the state goes for the care of the mentally deficient—that the only hope of coping with the situation is to attack it from the side of prevention.

In the last ten years, there have been admitted to the Massachusetts state hospitals 3096 patients under 25 years of age.

The majority of these have been cases of manic-depressive insanity and dementia praecox. Of the two, the cases of dementia praecox have no doubt predominated. The real cause of this disease is not yet known. There are those, notably Kraepelin abroad and Southard²⁵ of this state, who emphasize the somatic nature of the disease. There are others.—Freud abroad, Hoch, Meyer and Jelliffe in this country, who emphasize the psychic origin. We need not enter into that discussion. Two things at least appear evident: (1) that heredity plays an important rôle; that the disease develops upon a background, as it were, of bad heredity; (2) that

undue mental strain is frequently the precipitating cause. Physical strain precipitates the disease in a certain percentage of these cases. The nervous and mental mechanism of these latter individuals is so unstable that without any undue mental strain they go to pieces "on the rocks of puberty," as it were, or at other periods of physical strain. There is little hope of accomplishing much with this class. But if a study were made of the above 3000 young adults, it would be found that a certain fairly large percentage of them had broken down in high school, others in early collegiate years, and still others on a change from a comparatively uncompetitive village or rural life to a competitive existence in a large city. "An ill-directed ambition has stimulated children of psychically poor rural stock to take up intellectual pursuits in the urban centers. Dementia praecox is not an infrequent result," says Christian,²⁷ writing of conditions in France. Observations in our own hospitals demonstrate the same facts, except that we should place the indictment not only against the "psychically poor rural stock," but psychically poor stock, either rural or urban. "... for the adolescent with some of the hereditary factors already outlined," writes Jelliffe,²⁸ "it is a fact, the significance of which cannot be controverted, that fatigue is a highly important element in their mental breakdown."

The problem of prevention therefore becomes a problem of avoiding undue strain in susceptible individuals. And this raises the question as to how susceptible individuals may be known. The work of Meyer and Jelliffe on pre-dementia praecox stages, or the early personality study of dementia praecox cases is suggestive in this regard, and to those who feel a responsibility in this matter, I should recommend the study of these papers.²⁹ It is possible here to go into the subject but briefly. Two types of personality, it would seem, can be distinguished among these individuals, the so-called "shut in" personality, and the precocious. Many of those who come to the hospitals from the schools and colleges have been exceedingly bright students, frequently leaders in their classes, but there has been a restless feverishness about their work, an insatiable appetite for book knowledge and the accumulation of facts. The accumulation of facts gives them a show of brilliance, but the facts they have gathered are ill-judged and poorly synthesized or not synthesized at all. Such rapacious and unstable students should arouse suspicion. The other class presents much the opposite appearance—they are moody, frequently sullen, desire to be left alone, do not mingle with their mates, are day dreamy, inclined to immature philosophizing; prefer "thinking" to "doing"; frequently show unsteadiness of occupation and inefficiency, exhibit morbid interest in their bodies, are faddists in regard to such things as food, bath, exercise, are irritable without cause, sullen when opposed. In other words, these children are frequently the "queer" and "peculiar"

children. Not all dementia praecox cases exhibit these early signs. Bond and Abbot,³⁰ in a study of the early personality characteristics in dementia praecox and manic-depressive patients, concluded that normal personalities are found fairly frequently in both diseases; that abnormal personalities are much more frequent in dementia praecox; that certain abnormal traits—reticence, peculiarity, precocity—are found in much larger proportions in dementia praecox than in manic-depressive; and that the “shut-in” personality and the tendency to it is found almost exclusively in dementia praecox. Their final conclusion was, however, that not more than half of the dementia praecox cases exhibited these early personality traits. Granting that only half can be thus early differentiated, much room is still left for accomplishment.

If we may hope to prevent the ultimate breakdown of these children as they approach adult life, it is important that the family physician, who knows the family so well, should understand the significance of these early signs of danger ahead, so that where a child of known bad heredity is found exhibiting these traits, advice may be sought as readily and as freely as advice would be sought in a case of suspected tuberculosis. These children, urged on by their mistaken and ambitious parents to pursuits that are beyond them, go to pieces; while, so far as we know, many of these children directed into channels of less strain and competition might live out their entire lives without insanity. Is it not reasonable to hope, therefore, for the time when physicians will be as keen and careful and skilled in detecting the early signs of mental disease as they are now in detecting the early signs of tuberculosis, and when by a closer coöperation between the family, the physician and the hospital, these cases can be studied and the family be given proper advice as to the future safe training of the child? This coöperation is made possible by the present voluntary and temporary care laws.

In conclusion it may be said that the present voluntary and temporary care laws are valuable because:—

1. They tend to express in legal form the modern conceptions of mental disease; and without endangering the personal liberty of any individual.
2. They at the same time emphasize the patient's cause as a patient:
3. They make it possible to provide early treatment, which is the most hopeful treatment;
4. They afford protection to the patient both from himself and from unprincipled members of the community quick to take advantage of his illness;
5. They afford protection to the family and community against the acts of the patient;
6. They obviate in a large number of cases the delays, legal exactions, semi-publicity, and stigma of having been declared insane;

7. They remove the hospitals from the isolation they have suffered in the community and make it possible for them to take their place as hospitals in fact as well as in name, a more integral part of the social fabric;

8. They make possible a wider coöperation between the hospitals and the lay and medical public, which will yield to the Commonwealth which supports them a greater usefulness;

9. And finally, by means of a wider understanding of the more fundamental facts in regard to mental disease on the part of physicians, coöperating with the hospitals, through the more frequent use of these laws it may be possible to prevent certain forms of mental disease.

REPORT OF HARVARD UNIVERSITY SERVICE AT THE AMERICAN AMBULANCE, LYCÉE PASTEUR, NEUILLY-SUR-SEINE, FRANCE.

APRIL 1 TO JULY 1, 1915.*

BY ROBERT B. GREENOUGH, M.D., BOSTON.

At the request of the Medical Board of the American Ambulance at Neuilly-sur-Seine, a surgical contingent was organized by the Harvard Medical School, and sent to France to take charge of the so-called University Service of that hospital from April 1st to July 1st, 1915.

The funds needed for the equipment and transportation of this contingent, commonly known as the "Harvard Unit," were generously provided by Mr. William Lindsey of Boston, and the group of seventeen surgeons and nurses arrived in Paris on the morning of April 1st, 1915, and proceeded at once to take charge of the service which had been from January 1st to April 1st, under the care of Dr. G. W. Crile of Cleveland, and the members of the Western Reserve "Unit."

The American Ambulance was established as a military hospital for wounded soldiers, by the staff of the American Hospital of Paris, in September, 1914, and has been generously supported by Americans in Paris and at home. It is directly under the control of the Service de Santé of the French War Department, and is independent of the French, English or American Red Cross Societies.

The Lycée Pasteur, a high school building, still under construction, but nearly completed, in Neuilly, a suburb of Paris, was secured by the War Office and converted into a most excellent war hospital. Mr. Carroll Greenough, as representative of the firm of architects who built the Lycée, was in charge of these and subsequent alterations and improvements.

The Ambulance (the French word for a military hospital) was gradually enlarged until in June, 1915, it contained beds for over 750 patients. Of this number the University Service (Service D) had 190 beds, the rest being divided between three other services as follows: Service A, Dr. C. W. DuBouchet, Surgeon-in-chief; Service B, Dr. Joseph A. Blake; Service C, Dr. Mignon. In addition to these general surgical services special departments were also in operation, as follows: Dental Department, Drs. Hays and Davenport; Throat and Nose Department, Dr. Koenig; Eye Department, Dr. Scarlett; Genito-Urinary Department, Dr. Heitz-Boyer; X-ray Department, Dr. Jougeas; Pathological Department, Dr. Kenneth Taylor.

All of the administrative departments of a modern hospital have been established, such as kitchen, laundry, supply room, apothecary, diet

kitchen, and departments for statistics and surgical dressings and apparatus. There is a competent corps of trained nurses under the Superintendent, Miss Willingale. Many of the nurses have had their training in American or English hospitals, and there is a sufficient force to supply one nurse to every ten patients by day, and one for every forty patients by night. In addition to the trained nurses, and acting as assistants to them, there has been organized a corps of volunteer or auxiliary nurses and orderlies. These volunteers have given most devoted and competent service, and have contributed greatly to the comfort and well-being of the wounded. It is fair to say that without this efficient group of volunteers a much greater number of trained nurses would have been required, and the cost of maintenance of the hospital would have been that much increased.

The University Service was composed of eighteen wards, containing ten or eleven beds, on the third floor of the building. A special operating room and laboratory was arranged for this service on the fourth floor of the north wing, giving excellent light and ample and satisfactory equipment. No surgeon could reasonably ask for more favorable conditions under which to work.

The members of the Harvard University Service which took charge on April 1st, were as follows: Dr. Harvey Cushing, surgeon; Dr. Robert B. Greenough, surgeon and executive officer; Dr. Richard P. Strong, bacteriologist; Dr. Robert B. Osgood, orthopedic surgeon; Dr. Beth Vincent, assistant surgeon; Dr. William M. Boothby, anesthetist; Drs. Fred A. Collier and Elliot C. Cutler, resident surgeons. Drs. Philip D. Wilson, M. N. Smith-Petersen and Lyman G. Barton, Jr., house-officers; Dr. Orville F. Rogers, Jr., medical assistant; Dr. George Benet, laboratory assistant; Misses Edith I. Cox, Geraldine K. Martin, Helen A. Parks and Marion Wilson, operating-room nurses.

About April 10th, Dr. Strong was obliged to leave Paris for Sérvia, to take the position of director of the American Red Cross Sanitary Commission, and Drs. Rogers and Benet took over the laboratory work. On May 1st, Dr. Cushing and Dr. Boothby left for home, and on May 28th, Miss Wilson left for England. During a part of the month of April, Dr. Vincent was detached for service at a Red Cross hospital at Chateau-Annel, near Compiègne, to fill an urgent need. During the latter part of June, Dr. Wilson was transferred, temporarily, to Dr. Mignon's service to fill a vacancy in the house staff. With these exceptions the service continued as it started until July 1st.

The functions commonly exercised by the trustees of a hospital were fulfilled by the "ambulance committee" composed of the group of Americans resident in Paris, to whom the American Ambulance owes its existence. Laurence V. Benet, Robert Bacon, L. V. Twycelfort,

* Submitted by the Department of Surgery of the Harvard Medical School to the President and Fellows of Harvard College. Published in part in the issue of the *Harvard Alumni Bulletin* for Oct. 27, 1915.

Charles Carroll, Dr. Edmund L. Gros, Dr. Joseph L. Blake, Dr. C. W. DuBouchet, and Capt. Frank H. Mason were among the most active workers on this board. Under this committee were administered also the affairs of the two independent but allied institutions: "Hospital B," a war hospital of 200 beds, established at Juilly, under the financial support of Mrs. H. P. Whitney, and the "Ambulance Corps," an organization of 78 motor ambulances with volunteer drivers, which were assigned in squads of ten to twenty ambulances to work at different portions of the line, as ordered by the War Department, and which used the Lycée Pasteur as a base for equipment and supply. In June, 1915, a further extension of the hospital was also under way in the establishment of a convalescent home at St. Cloud, and the organization of a continuous orthopedic service.

The amount and quality of material for surgical dressings and supplies provided by the Ambulance was adequate for all surgical necessities. The Harvard Unit brought and supplied for its own use such special instruments and materials as would not readily be found in Paris—notably instruments and materials for Dr. Cushing's work, a "Connell" ether anesthesia apparatus, a supply of nitrous oxide and oxygen for anesthesia, orthopedic appliances, and a "Maddox" extension table for the application of plaster dressings to fractures. An estimate was made of the amount of gauze-sponges, pads, dressings and bandages necessary for the three months service, and the cost of the raw materials was contributed by the committee of the American Ambulance in New York. These materials were made up and sterilized by the surgical dressings committee of the Civic Federation of Boston, under Mrs. F. S. Mead, and packed and shipped to Paris in March and April. The first of these supplies reached Paris about April 10th, and from that time all the needs of the University Service were admirably supplied by these dressings. They arrived in excellent condition and in use they proved to have been efficiently sterilized.

A system of triplicate records with a card catalogue index was put in operation on the University Service on April 10th, as soon as the necessary blank forms could be obtained and stenographers employed. One copy of the record remained to be filed in Neuilly. Two copies with duplicate x-rays, charts and photographs have been brought to Boston and deposited in the library of the Harvard Medical School. To assist in the preparation of these records two stenographers and one photographer were employed. Records and notes were dictated daily, and manifold copies were typewritten and filed in envelope folders in the wards, as well as in the record room. For each case discharged from the hospital a special blank form, provided by the French War Department, had to be filled out, giving in brief the nature of the wound, its

treatment and complications, and the condition of the patient at discharge.

The supply of wounded to the American Ambulance was probably as constant as that to any of the French military hospitals, but, of course, varied with the activity of operations at the front. Being a base hospital it drew from a wide section of the front, and during our service cases came to us from as far north as the Franco-Belgian line beyond Ypres, and as far east as Verdun. Under ordinary circumstances a soldier wounded in the trenches has a first-aid dressing with iodine applied at his regimental dressing station. He is then carried or walks back to the "poste de secours," at the point nearest to the front to which ambulances can go. This "poste de secours" is situated either in a bomb-proof dug-out, or in a farm house or other building, and is often under artillery fire. No elaborate surgical interference can be undertaken under these conditions, but emergency dressings and splints are applied, and a tag is filled out giving the name and corps of the soldier, a provisional diagnosis, and a statement of whether he has had, or is to receive, a prophylactic dose of anti-tetanic serum.

The patient is then moved in a cart, or, if possible, in an ambulance back to the "ambulance de première ligne," just out of artillery range. Here a surgeon investigates the wound, gives a dose of anti-tetanic serum if necessary, and operates on such cases as require imperative interference, as for hemorrhage or abdominal injuries. The equipment is necessarily inadequate, and the majority of cases pass rapidly through the first line hospital to the evacuation hospital on the railway line. Here they are again inspected, urgent operations are performed, and the cases placed as soon as possible on the "sanitary train" and sent to Paris, or to some other centre of distribution. The sanitary trains are admirably fitted out with stretchers for the "grandes blessés" and seats for the "petits blessés" or ambulatory cases. A corps of surgeons and orderlies is assigned to each train, and the cars are used for no other purposes. By each of these trains 250 to 300 wounded can be transported rapidly to the base. In Paris the trains arrive at La Chappelle, the freight station of the Gare du Nord. Here a long freight shed has been converted to hospital purposes, the track is curtained off, and portable houses have been erected on the platform for the medical officers, and the different classes of wounded. The shed is warmed with open braziers, and bright and cheerful with potted plants. A squad of Red Cross nurses is at hand to supply food and drink, and to assist in the adjustment of dressings, and in the distribution of the wounded. Outside, behind a barrier, the ambulances from the different Paris hospitals are drawn up, often as many as one hundred, to meet one train, and the ambulance drivers wait in a separate enclosure to get their assignment of wounded.

As fast as the wounded are brought off the train they are assigned to the different hospitals according to the day's list of vacant beds. Some room for selection is possible on account of the nature of the hospitals. German prisoners are sent to the regular military hospitals, such as Val-de-Grâce, where they can be under guard. Insane patients are also sent to a special hospital. Medical cases are sent to one institution, and grave surgical cases to others. In this distribution the American Ambulance receives due recognition, and its wards are kept practically full with the graver surgical cases. During Dr. Cushing's stay, a special effort was made to send cerebral cases to the Ambulance.

The sanitary trains arrived in Paris at all hours of the day or night, as the exigencies of traffic to and from the front permitted. The motor ambulances would then bring the wounded to the hospital. The receiving clerk and the surgeon of the day would examine the patients and assign them to the wards. Each of the four services receives all of the cases coming to the Ambulance every fourth day in rotation, but when the hospital was nearly full, cases might be sent to any service where there were vacant beds. The largest number of admissions to the University Service in any one twenty-four hour period was thirty-three. In the three months' service 295 new cases were allotted to us,—an average of over three cases a day. On April 1 the University Service had 146 patients. During April 138 new cases were admitted and 131 discharged. During May 103 cases were admitted and 95 discharged. During June, 54 cases were admitted and 41 discharged. A total of 295 admissions and 267 cases discharged.

Of the total number of 441 cases which at one time or another came under the charge of the Harvard University Service we have 383 records. No records were obtained of 58 cases which were transferred to us by the Western Reserve Unit, but were discharged from the hospital before stenographers had been secured and a permanent system of records established. Forty-seven of this number had been officially discharged from the hospital on April 1, but had not then actually left the building.

Mortality: Of the 441 cases entered on the Harvard University Service, in the three months from April 1 to July 1, 1915, seven died, or 1.6%. The causes of death in these cases were as follows:—

CASE 1224. Bullet wound of spinal cord and chest. Paralysis, bed-sores, exhaustion.

CASE 1946. Bullet wound of intestine. General peritonitis and hemorrhage. Died fifteen minutes after entrance to hospital.

CASE 1671. Shell wound of chest and laceration of lung. Hemo-pneumothorax.

CASE 2146. Compound fracture and gangrene of arm. Gas-bacillus infection. Immediate amputation. Gas-bacillus septicemia.

CASE 1726. Compound fracture of skull: laceration of brain. Meningitis.

CASE 1737. Compound skull fracture by rifle ball; laceration of brain. Erysipelas; meningitis.

CASE 2139. Compound fracture of jaw and cervical vertebrae by shell fragment. Meningitis.

The 383 cases included in the records of the Harvard University Service were divided as follows:

Single wounds.....	217
Two or more wounds.....	101
Amputation wounds.....	4
Sepsis.....	3
Diseases of ears.....	5
Diseases of teeth.....	12
Diseases of eye.....	1
Doubtful diagnosis.....	1
Miscellaneous diseases and injuries without wounds.....	39
Total.....	383

Three hundred and seventeen of the 383 cases received actual wounds by missiles. They were divided as follows:

Rifle ball.....	128
Shrapnel ball.....	31
Shell fragment.....	133
Shell fragment and rifle ball.....	5
Shell fragment and shrapnel.....	1
Doubtful.....	5
Bomb fragments.....	9
Hand-grenade wounds.....	3
Mine explosion.....	1
Revolver ball.....	1
Total.....	317

Of the 66 cases in which no wound produced by a missile existed, the nature of the injury or disease was as follows:—

Falls.....	15
Barbed wire wound.....	1
Bomb, shell and mine explosions.....	10
Crushes.....	3
Miscellaneous diseases and injuries.....	37
Total.....	66

Considerable interest attaches to the question of whether a missile perforates the body and makes a wound of exit, as well as one of entrance, or whether the missile lodges in the tissues. It would be expected that the rifle ball would perforate more frequently, and that shell fragments and shrapnel balls, having a lower velocity, would show more tendency to lodge in the tissues.

Of 154 wounds by bullets 128 were perforating wounds and in 26 the bullet lodged—16.8%.

Of 32 wounds produced by shrapnel balls 17 were perforating and in 15 the missile lodged—46.8%.

Of 161 wounds produced by shell fragments 89 were perforating and in 72 the fragments lodged—44.7%.

Many of the 383 cases included in the records

of the Harvard University Service presented more than one wound, and in many more several different anatomical structures were affected. These different lesions were classified and studied separately, giving data on some 670 instances of special medical or surgical conditions. A brief analysis of these groups of cases is appended.

Group 1. *Injuries and Diseases of the Skull*—20 cases. These were all compound fractures of the skull, in 15 of which cerebral symptoms developed, and in 5 there were no cerebral symptoms. Two cases were not operated upon; 9 were operated upon in other hospitals, and 9 in the American Ambulance. In 10 cases of skull injury the missile lodged, and in 4 cases the missile was removed by operation—in 2 cases by the use of the electro-magnet. Two cases (No. 1726 and No. 1736) died; the rest recovered.

Group 2. *Injuries of the Spinal Cord*—7 cases. In 6 cases there was injury by missile to the vertebral column. One case was merely concussion. There were 4 operations performed, and in 2 cases a hematomyelia improved without operation. There were 2 deaths—No. 1224 of toxemia and No. 2139 of meningitis.

Group 3. *Injuries of the Head and Face*—14 cases. Superficial wounds of the face, 8; scalp wounds, 4; 1 case of wound of the orbit and antrum, and 1 case of fracture of the teeth. There were no fatalities among these cases.

Group 4. *Fractures of the Upper and Lower Jaw*—63 cases. Injuries of this region appear to be extremely common under present conditions of trench warfare. Practically all of these cases were treated in the Dental Department, and seen by the surgical staff only in consultation. The work of the dentists in these cases is one of the remarkable features of the medical work of the Ambulance. Interdental splints, crown and bridge work, wiring of teeth, with and without metal splints, massage, and the use of inclined planes are some of the methods used to bring about reduction of misplaced teeth and alignment of the jaws. Six of these cases were returned to the University Service for operation for the repair of defects of the lips and mouth. One case had a bone graft (rib) placed to fill a defect in fracture of the lower jaw.

Group 5. *Fractures*. Compound fractures with more or less sepsis were perhaps the most important and difficult cases of the Service. There were 121 compound fractures and 19 closed fractures. Omitting 5 cases of compound fracture of the phalanges, there were 13 cases in which amputation of an extremity was necessary. Five were amputated in other hospitals before entrance to the Ambulance; 2 were amputated on the University Service before the Harvard Unit came on duty. The 6 amputations performed on the Harvard Service were as follows: For secondary hemorrhage, 2 cases; for gas-bacillus infection, 1 case; for sepsis of the knee and ankle joint, 3 cases. One of these cases—a gas-bacillus infection—died of septi-

cemia, although the amputation was performed immediately on entrance. There were no other fatal cases.

Most of these compound fractures were septic at entrance, and the general policy of treatment adopted involved the investigation, under an anesthetic, of every compound fracture, with removal of foreign bodies, such as shell fragments and clothing, and of detached bone fragments. There were only three cases of compound fracture in which aseptic healing of the wounds of entrance and exit occurred. These were: (1) fracture of the neck of the femur; (2) fracture of the fibula; (3) a fracture of a phalanx.

Of the 19 closed fractures, 2 cases of fracture of the femur, and 3 of fracture of the tibia were operated upon for mal-union and fixation with bone-plates or Parham bands attempted. All of these cases healed by first intention. In one case a plate loosened and there was a partial recurrence of deformity. In the other 4 cases the results were entirely satisfactory.

With the exception of the 6 cases which came to amputation the compound fracture cases made satisfactory progress, and a number were able to do without apparatus on July 1st. Many of the cases, however, were still under treatment with apparatus on that date.

In 42 of the fracture cases neighboring joints were involved—40 compound and 2 closed fractures. In 6 of these cases excision of the joint was performed—4 of the shoulder, and 2 of the hip.

Group 6. *Injuries of the Chest*—21 cases. In 2 cases only the ribs and soft parts of the chest wall were injured and the pleural cavity was not involved. In 9 the missile passed through the chest cavity, with wounds of entrance and exit, and in 10 the missile lodged. Eleven of the 19 pleural cases developed empyema, and 10 recovered. One case that died (No. 1224) was a spinal paralysis case with death due to bed-sores and exhaustion. One case died of hemorrhage into the pleura from a lacerated lung. Five of the 11 empyema cases were operated upon by rib resection; others had sufficient drainage provided by the original wound, or had healed to a small sinus, when they entered the hospital, and did not require further drainage. In 2 cases the posterior mediastinum was involved.

Group 7. *Injuries and Diseases of the Abdomen*—13 cases. There were 7 penetrating wounds of the abdomen. One case (No. 1946) died fifteen minutes after entrance to the hospital, of general peritonitis. Two developed fecal fistula, one of which was closed by operation and healed by first intention. Three cases of abscess in the lower abdomen resulted, which were drained. Three cases of sub-acute appendicitis were operated upon, and all healed by first intention. One femoral and one inguinal hernia were also operated upon successfully. There was one case of abdominal contusion which recovered without operation.

Group 8. *Injuries of the Pelvis*—4 cases. One was a simple fracture; the other 3 were perforating wounds, one of which involved the rectum. All of these wounds were drained.

Group 9. *Peripheral Nerve Lesions*—39 cases. Twenty-two of these had accompanying bone lesions. Of the peripheral nerves the musculo-spiral was the most commonly injured. There were 10 cases. The median nerve and the external popliteal nerve were each affected in 5 cases. Twelve operations were performed for peripheral nerve lesions—7 sutures, and 5 exploratory operations for freeing the nerve from scar contraction. All of the wounds healed by first intention, but sufficient time had not elapsed to determine the extent of return of function. Five cases showed improvement of function before July 1.

In addition to operative treatment, massage, electricity and supporting apparatus were used. Supporting or "cock-up" splints were devised by Dr. Osgood for 7 cases of wrist-drop, and special wire splints for 3 cases of toe-drop.

Group 10. *Joint Lesions without Fracture*—13 cases. There were 7 penetrating wounds of joints; 4 of these were of the knee joint; 2 were old cases with continued drainage and ankylosis; 2 were fresh cases in which temporary drainage to the synovial membrane was employed, and these healed without loss of motion. There were 2 cases of lesion of the hip joint in which missiles lodged in the vicinity of the joint and subsequent sepsis invaded the joint. There was one case of temporary drainage of the elbow joint, without loss of motion. There were 6 cases of sprains or synovitis without external wounds, all of which subsided with strappings or plaster, and later massage.

Group 11. *Lesions of Soft Parts—Skin, Muscle, Tendon*. In some cases several missiles (as shell fragments) produced multiple wounds in the same individual. In others one missile produced multiple wounds in the same individual. In one instance eight wounds were produced in one individual by a single rifle ball, viz: right thigh (entrance and exit), penis (entrance and exit), scrotum (entrance and exit), and left thigh (entrance and exit). We have records of 378 wounds in our 383 cases, exclusive of 30 cases of multiple injury in which there were more than five wounds, and an accurate enumeration of them was difficult or impossible. One hundred and twenty-one of the 378 wounds were associated with bone lesions. The remaining 257 were wounds of the skin and soft parts alone. In general all of these wounds were septic.

Cultures: An effort was made to obtain cultures of all fresh open wounds, and cultures were obtained in all cases in which there was the possibility of grave infection. We have records of 132 cultures taken on a hundred different cases. Twenty-eight of these cultures showed anaerobic gas-producing organisms, not to be distinguished from the *Bacillus Aerogenes* Cap-

sulatus of Welch. Other anaerobes were occasionally present, and there were many cultures showing the ordinary pus-producing organisms. A report upon the bacteriological findings of the Service will be made in full by Drs. Rogers and Benet, who were in charge of the laboratory.

The treatment adopted for wounds of the soft parts was in general similar to the treatment of compound fractures. Under an anesthetic a thorough cleansing of the wound was obtained with benzine and iodine on the skin, and sodium hypochlorite for irrigation. Sloughing and damaged tissues were removed, and in the majority of cases drains were inserted. In 3 cases primary suture of an infected wound was attempted, after cleaning, and in 2 of these cases healing by first intention resulted. In 5 cases secondary suture was performed after the case had been in the wards for some days, and in 5 of the 6 the sutures held and the wound healed practically by first intention.

Muscles and tendons were involved in wounds of the soft parts in 55 cases, 43 of which were operated upon for cleansing and drainage. In 17 cases plaster or splints were used for fixation of these wounds, and in 8 cases contractions of muscle occurred, as a result of healing of these wounds.—3 of the ham-string muscles, 3 of the calf muscles, 1 of the biceps of the arm, and 1 of the extensors of the forearm. In 2 cases manipulation under an anesthetic was required, and in 1 an open operation for lengthening the tendo Achillis.

Of the 257 wounds of the skin and soft parts without bone involvement 10 healed aseptically and without interference, and 2 after operative cleansing and suture. The other wounds were all treated with drainage and did not heal "per primam."

Group 13. *Miscellaneous Lesions*—49 cases. A number of injuries and diseases presented themselves which do not fit in the groups which have been above described. Some of these conditions occurred only as intercurrent or complicating diseases. The list is as follows:

Diseases of the teeth and gums.....	12
Diseases of the ear.....	8
1 ruptured drum	
7 otitis media (2 of these required mastoid operations)	
Injuries and diseases of the eye.....	7
Septic processes not due to wounds.....	3
Frost-bite	2
Cardiac lesions	2
Bronchiectasis	2
Syphilis	2
Mesenteric tuberculosis	1
Chronic ulcer of leg	1
Sprain of back	1
Burn of neck	1
Typhoid fever	1
Broncho-pneumonia	1
Pneumonia and malaria.....	1
Bronchitis	1
Influenza	1
Foot deformity	1
Doubtful diagnosis	1
Total	49

There were no deaths in this group of cases.

Group 14. *Medical Work.* The medical work of the Service was conducted by Dr. Orville F. Rogers, Jr. It consisted in large part of chest examinations in cases of wounds of the thorax, in the study of a number of cases of obscure diagnosis, and in the regulation of the diet in cases of general debility, and in cases of jaw injury which interfered with proper mastication. In all, forty-four different morbid conditions were referred to the medical assistant for examination and treatment.

Group 15. *Operations.* There were 210 different cases operated upon in the University Service, and 271 operations were performed. The list is as follows:—

Exploration for compound fractures.....	37
Exploration for foreign bodies.....	22
Incision, cleaning and drainage of septic wounds	127
Craniotomy	10
Mastoid operation.....	1
Drainage of antrum.....	2
Operations on peripheral nerves.....	4
Laminectomy	1
Operations on the chest:	
Aspiration	1
Rib resection	3
.....	4
Operations on the abdomen:	
Appendectomy	3
Hernia	2
Closure of fistula	1
.....	6
Amputations:	
Finger	12
Arm	12
Leg	12
Thigh	8
Re-amputation with disarticulation	
(shoulder joint)	1
Plastic operations on face and jaw.....	14
Plastic operation on tendon.....	1
Plastic operation on bone cavity.....	1
Skin graft	1
Secondary suture	8
Fixation of closed fracture with bone plates.....	5
Removal of bone plates.....	2
Excision of chronic ulcer.....	1
Manipulation and plaster.....	7
Resection of finger joint.....	1
Resection of shoulder joint.....	3
Resection of hip.....	2
Transfusion	2
Total	271

In no case of operation in a clean field was there failure to obtain first intention healing.

On Thursday, July 1, 1915, the cases of the Harvard University Service were transferred to the University of Pennsylvania Service, under Dr. J. P. Hutchinson, and the members of the Harvard Unit left Paris that night and sailed on Saturday, July 3rd, from Bordeaux, arriving in Boston Tuesday, July 13.

A number of shell fragments, cartridges, bullets and other missiles were brought back, together with a large number of photographs and the records of the University Service. These have been delivered to the Warren Museum, and will be properly mounted and labeled for teaching purposes.

Lantern slides have been made of the more important photographs.

A more extended report upon the surgical aspects of the work is in preparation and will be published in the fall.

Original Articles.

ARTIFICIAL PNEUMOTHORAX.*

By EDWARD O. OTIS, M.D., BOSTON.

HARDLY any new procedure in medicine or surgery has come into such prominence within the last few years as artificial pneumothorax. The literature upon the subject is now quite enormous—whole issues of medical periodicals have been devoted to it. It was one of the main topics for discussion in the last International Tuberculosis Congress at Rome. An International Artificial Pneumothorax Association has been formed which disseminates literature upon the subject. There is hardly a sanatorium or consumptive hospital in which the operation is not done. Experience and knowledge upon the subject have, therefore, accumulated rapidly, and we are in a position to form a fair estimate of its value from results.

After Forlanini, the pioneer and ardent advocate of this treatment, we are perhaps more indebted to Brauer of Hamburg than to any other single investigator of this form of treatment, for bringing the subject definitely before the medical public which is occupied in the management of pulmonary tuberculosis. There is a wealth of clinical experience in the marvellously minute and painstaking histories of the one hundred cases which he published in 1911, cases extending over a period of five years. We hear much of German efficiency and attention to details in these days. Surely, Brauer's work is an admirable illustration of this Teutonic characteristic, and no one who desires to become familiar with the subject can afford to neglect his work, although his method of operation has now fallen into disuse.

From the extensive evidence at hand from all over the world, no one can now deny the value of artificial pneumothorax in pulmonary tuberculosis when other means fail. In some cases it brings about an arrest of the disease not otherwise attainable; in other cases, a relief from one or more of the distressing symptoms. Its applicability is limited, in my opinion, and it is often unsuccessful. As Balboni well says, "it is an unusual therapeutic measure, the creation of a pathological condition in order to cure or relieve another pathological condition," and is "only to be undertaken after careful consideration of each individual case."

* Presented in discussion at the meeting of the National Association for the Study and Prevention of Tuberculosis, Seattle, Wash., June 15, 1915.

In general, there is a unanimity of opinion among those of the most experience as to the indications for applying this treatment: extensive unilateral (or chiefly so) progressive or chronic lesions which fail to respond to the ordinary hygienic-dietetic treatment, or to tuberculin. Second: recurring more or less severe hemoptysis which fails to yield to ordinary treatment, or very severe hemorrhage not otherwise controlled, provided, of course, one can be sure from which lung the hemorrhage comes.

All of Brauer's cases, as he says, were those in which the conditions and progress of the disease gave an absolutely unfavorable prognosis. "If you are to judge of the results of the treatment with artificial pneumothorax," says Saugman, "it must at once be understood that this treatment deals with very severely attacked, third stage patients of whom a great part, indeed, most of them, without this treatment would have practically no chance of recovery or healing."

There seems to be some diversity of opinion and practice, however, in regard to the two extremes, the earlier cases and the last stage ones. Pneumothorax therapy is by some recommended for early or incipient cases which appear to have no recuperative power or show no improvement under the ordinary treatment; also in early cases which have no opportunity for the usual open-air treatment; or again, when the "progress toward improvement is particularly slow." At the other extreme, this treatment is employed by many in otherwise hopeless or doomed cases as a last desperate resort whenever compression can be consummated, and occasionally an arrest is obtained.

There seems to be no doubt that the unilateral cases with but little or no infiltration in the other lung, and that inactive, and where there is still a fair amount of resistance, offer the most favorable conditions for this treatment and give the best results. The percentage of such cases which are either arrested or greatly improved is placed as high as forty or fifty per cent. (Floyd).

To assume that if the operation does no good it will do no harm is, I believe, false; for there is always the possibility of pleural shock, gas embolism, subcutaneous emphysema, infection of the pleural cavity, disturbance of the blood supply from displacement of the heart, and a lighting up of the inactive process in the other lung. It is an operation that should only be entered upon advisedly, discreetly and in the fear of these possible dangers. One must also bear in mind that although he may consider the operation a very simple one, to the patient it means an *operation*, with all the dread that the word suggests, and he will not infrequently elect to take his chance without it when it is advised rather than undergo the mental anguish which the fear of an operation produces. This fact again reduces the number of cases to which we can apply the pneumothorax treatment.

A word with regard to the x-ray. The consensus of opinion is, I think, that one is not justified in carrying on the treatment without constant access to the x-ray with a skilled technician. Before beginning the inflation a careful study of the x-ray picture of the lungs should be made and subsequently, both before and after each inflation; only in this way, by ocular evidence, can we be sure that the case is a favorable one for the treatment, and determine its success. Moreover, we can thus avoid many of the dangers incident to it.

As to the apparatus employed, there are almost as many kinds or modifications of one or another kind, as there are operators. The main requisite is to use an instrument with which one is familiar, and which is as simple as the conditions will allow. Whatever the apparatus used, it should have a good manometer which can be easily read, and an arrangement whereby the flow of gas can be readily regulated as to pressure, and be steady. One of the most satisfactory forms of apparatus which has come under my observation is that of Prof. Deneke of St. George's Hospital, Hamburg. In brief, it is made double. Upon one side of an upright standard is a complete arrangement for the injection of nitrogen gas, and on the other side is a replica of the same for the injection of oxygen gas. Prof. Deneke's idea being that greater safety is insured if on the first injection oxygen is used, so that if by any chance the needle may have entered a vessel, the oxygen gas on account of its rapid absorbability will be much less likely to produce gas embolism. By simply turning a stop-cock, nitrogen gas can be substituted for the oxygen gas.

There have also been as many kinds of needles as apparatuses, each operator having his favorite one. Deneke's needle seems to me to have certain advantages, its peculiar characteristics being its extreme simplicity, consisting of a cannula and stylet, the cannula having a less acute angle at its perforating end than the ordinary needle, and is closed at this extremity, the opening being in the side just above the point.

There are many other problems in connection with artificial pneumothorax which could with great interest be discussed if time permitted; such, for example, as the amount of positive pressure permissible in case of adherent pleura, the amount of gas introduced at any one time and the frequency of introduction, the length of time the treatment should be continued, the effect upon the neighboring organs, the contraindications, and the employment of the treatment in recurring pleuritic effusions, bronchiectasis, and abscess.

The scope of artificial pneumothorax is apparently not yet fully determined, but that it has won a permanent place in the treatment of tuberculosis is assured. In the very conservative words of Saugman, "it has fully justified its place in the treatment of some severe cases of

pulmonary tuberculosis and that, by it, recovery sometimes may be obtained when any other treatment would have failed." It is well to bear ever in mind, however, that it does not by any means take the place of the well known measures for increasing and maintaining the resistance, such as fresh air, rest and good and sufficient food, but, like tuberculin, it is an additional aid in certain cases and may save the day.

ON THE STATE OF THE RESPIRATORY MECHANISM IN PNEUMONIA.

BY J. H. MEANS,¹ L. H. NEWBURGH,² AND
W. T. PORTER.³

[From the Laboratory of Comparative Physiology in the Harvard Medical School.]*

I.

It is known that when an animal breathes through a closed system of tubes, the amount of the carbon dioxide in the inspired air progressively increases. In normal animals the volume of the tidal air, *i.e.* the volume of the air passing in and out of the chest, increases with the increase in carbon dioxide until the reaction ceases. In our observations, the reaction of normal animals continued usually until the volume of the tidal air was four or five times greater than when the animal breathed only atmospheric air; in our highest observation, the increase was seven-fold, at which point the animal was still reacting. The increase of carbon dioxide in the inspired air is, therefore, a stimulus to the respiratory mechanism, and the state of that mechanism may be measured by determining the ratio of the tidal air (cubic centimetres per minute) to the percentage of carbon dioxide inspired.

It is the object of this investigation to compare this ratio in normal animals with the ratio in animals with pneumonia. The state of the respiratory mechanism in pneumonia will thus be revealed.

II.

The present experiments were performed upon cats.⁴ The percentage increase in the tidal air due to the progressive increase in the carbon dioxide breathed was found to be as follows: (Table I.)

TABLE I.—THE AVERAGE REACTION TO CARBON DIOXIDE IN NORMAL AND PNEUMONIA CATS.

Carbon Dioxide in the In- spired Air.	Increase in Volume of Tidal Air in Normal Cats.	Increase in Volume of Tidal Air in Pneumonia Cats.
Per Cent.	Per Cent.	Per Cent.
1	21	6
2	51	14
3	102	36
4	173	68
5	276	53

It is clear from Table I that the reaction of the respiratory mechanism to carbon dioxide is greatly diminished in pneumonia.

The greatly impaired reaction of the respiratory mechanism in pneumonia is admirably shown also by a comparison of the normal reaction with (*a*) that of animals moderately ill with pneumonia, and (*b*) that of animals near death with this disease. When the carbon dioxide in the inspired air rose to three per cent., the volume of the tidal air increased:

In normal animals.....	98%
In animals moderately ill with pneumonia.....	43%
In animals near death with pneumonia.....	7%

Since the volume of the tidal air in animals with pneumonia is often greater than the tidal air in normal animals, it might be supposed that pneumonia animals do not increase their respiration when stimulated by carbon dioxide because they are already breathing as much as they can. That this is not a source of error is demonstrated by comparing the carbon dioxide reaction of animals whose tidal air at the beginning of the observation has in every case approximately the same volume. Following is such a comparison:

When the carbon dioxide in the inspired air was two per cent.:

4 normal cats breathed.....	1223 c.c. per minute
4 pneumonia cats breathed.....	1233 c.c. per minute

Thus the tidal air in both groups was practically equal in volume.

When the carbon dioxide in the inspired air rose to four per cent., the same

4 normal cats breathed.....	2330 c.c. per minute
-----------------------------	----------------------

but the

4 pneumonia cats breathed.....	1758 c.c. per minute
--------------------------------	----------------------

Thus at two per cent. the pneumonia cats and the normal cats breathed alike, while at four per cent., the pneumonia cats had increased less than half as much as the normal cats.

III.

CONCLUSION.

1. The reaction of the respiratory mechanism to carbon dioxide is greatly diminished in pneumonia.

2. The graver the disease the less the reaction.

¹ Henry P. Walcott Fellow in Clinical Medicine, Harvard University.

² Dulton Scholar in the Massachusetts General Hospital.

³ Professor of Comparative Physiology, Harvard Medical School.

⁴ The state of the respiratory mechanism in dogs with pneumonia is now being studied. The results will be published with the full report of the present experiments.

* Aided in part by a grant from the Proctor Gift.

NOTE CONCERNING EXERCISE IN THE TREATMENT OF SEVERE DIABETES.

BY FREDERICK M. ALLEN, M.D., NEW YORK.

[From the Hospital of the Rockefeller Institute for Medical Research, New York.]

AUTHORITIES on diabetes have agreed that muscular exercise is a useful means of increasing tolerance in cases of mild or moderate diabetes, but is inadvisable in the most severe cases, where it may increase glycosuria, exhaust strength, and even send the patient into coma. It has been a stringent rule that severe diabetes should be guarded against all excessive exertion and fatigue.

Since the changes in diabetic treatment now transform severe into mild cases as far as freedom from glycosuria and acidosis is concerned, it was considered worth while to investigate whether such patients might also react to exercise in the same way as mild cases. Tests were made first on diabetic dogs, with a known constant limit of tolerance for carbohydrate or protein. It was found that vigorous exercise on the treadmill markedly raised the tolerance of such animals, as judged by the sugar in both urine and blood. In some experiments, dogs which for months past had regularly shown glycosuria whenever they were given 100 grams of bread, on exercise became able to take 200 grams of bread as a regular daily ration without glycosuria.

The tests with patients are more recent, but the results thus far appear sufficiently favorable to warrant recommending exercise as an addition to the treatment. Just how early the exercise is begun may vary with individual patients. It seems possible that the stronger patients may shorten their initial fast by this means if desired. As soon as the first few days of treatment have markedly reduced glycosuria and ketonuria, the dangers previously feared from over-exertion are apparently removed. Naturally, some of the severest cases are too weak for exercise at first, but it is begun as early in the period of dieting as practicable, and generally the weak patient is able to do more than he or his physician supposed. In suitable cases the blood-sugar may be found to fall rapidly during a half-hour or hour of lively exercise. In the earlier or more severe cases it may rise thereafter; but often it will continue to fall after the exercise is ended, and remain for some time at a lower level. In a patient free from glycosuria with persistent hyperglycemia, one fast-day with exercise may reduce the blood-sugar as much as several fast-days without exercise. If glycosuria is produced in a patient by adding either carbohydrate, protein, or fat to the diet, it is frequently possible to abolish this glycosuria by exercise while continuing the increased diet.

It seems advantageous to give exercise especially after a meal containing carbohydrate or

other food tending to produce glycosuria, although, when patients are able, they exercise at all times of the day. At present, short periods of vigorous exercise with rests between are preferred to long slow walks, which might tire the patient even more. The exercises now suggested are running up and down stairs, jumping rope, throwing a heavy "medicine ball," and turning somersaults. Tennis and other hard games should probably be beneficial. At first, precautions may be taken against the nervousness and sleeplessness sometimes caused by over-weariness in weak patients. Otherwise, patients are worked right up to the limit of their strength, somewhat like athletes in training. In regard to the reduction in weight which has been advised in the fasting treatment, the question has arisen as to what kind of tissue it is desired to reduce. The answer seems to be that it is desirable to reduce fat and reserve tissues, and build up active muscular tissue. With this end in view, the emaciated, flabby-muscled diabetic is turned into an athlete as far as practicable. During exercise, no attempt is made to shield the patient against excitement, invigorating cold, or any similar influences previously dreaded in diabetes. It is hoped that an end may be put to the period of pale, feeble diabetics, dressed in double underwear while hugging the radiator and growing more neurasthenic all the time. Some of the exercises above mentioned are planned to shake up these patients and break up their former bad habits, both physically and psychically. The patients feel much better; they are kept occupied during the day, and sleep well at night. Hunger may be partly satisfied by vegetables and bran cakes, but in general exercise has increased appetite less than it has increased the power to satisfy appetite. The patients can take a somewhat more liberal diet, and enjoy the possession of somewhat greater weight and strength; but the increase of weight in this instance consists of muscle not fat.

It is hoped that this addition to the treatment of severe diabetes will prove of especial value to children, to patients with persistently low tolerance, and perhaps to some of that class previously so hopeless, viz. tuberculous diabetics. For the ordinary type of patients it may be a means of getting results somewhat more quickly and thoroughly, and leading to a higher degree of both comfort and usefulness. The value of exercise is strictly limited. It cannot raise tolerance very high, and it is not equal to the dietary regime in importance. Results will be unfortunate if it is used merely as a means for shortening the hospital care of the patient, or for building up weight and strength at the cost of more important considerations. The radical and permanent control of the diabetes is the essential matter, and is to be judged by such things as glycosuria, acidosis and blood-sugar, not by a temporary sense of well-being. A stern program of fasting, low diet, and reduction of weight is still necessary as before, but it is hoped

that results may be more beneficial with the use of exercise as an additional detail of the treatment. The experiments with exercise are still in progress and will be published in detail later, together with a discussion of their theoretical bearings.

A STUDY OF THE STATISTICS OF THE NEW YORK STATE HOSPITALS FOR 1913, WITH SPECIAL REGARD TO STATISTICS REGARDING DEMENTIA PRAECOX.

By CHARLES T. LA MOURE, M.D., LAKEVILLE, CONN.,

Superintendent of the Connecticut Training School for the Feeble-Minded.

On carefully studying the statistics of the New York State Hospitals for the year ending September 30, 1913, we find that 8269 patients were admitted, and 7294 were discharged, leaving a surplus of 975 patients. Of the number admitted there were 1021 cases of dementia praecox first admissions, or practically one-eighth of all admissions.

Of these 1021 cases of dementia praecox the following are the number and type of cases:

- 542 paranoid type (249 men; 293 women)
- 46 katatonic (39 men; 7 women)
- 299 hebephrenic (183 men; 116 women)
- 98 simple (59 men; 39 women)
- 16 unspecified (8 men; 8 women)

The greatest number of dementia praecox cases admitted, 233 (152 men; 81 women), were between 20 and 24 years of age, and 84 cases admitted (48 men; 36 women) were between 15 and 19 years of age. There was no history of insanity found in 537 of these cases (290 men; 247 women) or over 50%. There was no history of alcoholism found in 598 cases (298 men; 300 women), and no history of alcohol ascertained in 256 more of these 1021 cases. There was no history of any nervous disease found in 408 cases and none ascertained in 562 cases.

It is interesting to note that 718 of these cases were unmarried (438 men; 280 women) and that 228 cases were married (76 men; 152 women). Of these cases 643 (323 men; 320 women) had a common school education, seventy cases a high school education (36 men; 34 women) and 18 had a collegiate education (9 men and 9 women). Of these 1021 cases only 308 were classed as constitutionally inferior or defective (152 men and 156 women). There were discharged from the New York State Hospitals for the same year 606 cases of dementia praecox, of this number only 16 cases as recovered; 126 as much improved; 243 cases as improved; 221 cases as unimproved. As the statistics do not give the length of hospital residence of the discharged cases, certain deductions cannot be made.

During the same year 548 cases of dementia

praecox died—the greatest number (65) were between 35 and 39 years of age. The average age at death was: men, 46.8; women, 51 years or 49 years. The average length of hospital residence was 14.9 years for these 548 cases. One hundred and seventy-five of these cases died of tuberculosis of the lungs. The greatest number of deaths was from dementia paralytica (634 cases) and the average hospital residence was 1.4 years. There were 537 deaths among the senile cases, and their average hospital residence was 2.9 years. One hundred and eleven alcoholic cases died, and their average hospital residence was 5.1 years. One hundred and ninety-two manic depressive cases died, and their average hospital residence was 4.7 years. Seventy-seven cases of involutional melancholia died, and their average hospital residence was 4.5 years.

It cost the state \$200 per capita in 1913. If we look at these statistics from a financial point of view we find that the 548 cases of dementia praecox whose average life in the hospital was 14.9 years have cost the state \$1,633,040.00, while the senile cases cost only \$311,460.00. The 634 cases of dementia paralytica cost but \$177,520.00; the 192 cases of manic depressive, \$180,480.00; the 111 alcoholics, \$113,220.00; the 77 cases of involutional melancholia, \$69,300.00.

Of these 1021 cases of dementia praecox the paranoid form was most prevalent, as there were 543 of that type, and 45 more women than men so diagnosed. There were 98 cases of simple dementia praecox (59 men; 39 women), 299 hebephrenic type (183 men; 116 women), 67 more men of this type than women. Now with such a large number of first admissions diagnosed as dementia praecox, with 547 cases less than thirty years of age, with no history of insanity in 537 cases; no history of alcohol in 598 cases, and unascertained in 256 more cases, with only 308 cases of the 1021 cases classed as constitutionally inferior—with a history of 643 cases having had a common school education, 70 a high school, and 18 a collegiate education, does it not seem as if something more could have been done to relieve this form of mental disease—that special study should be devoted to this subject; especially as the pathologists have found no definite pathological change in the brains of cases of dementia praecox?

Some pathologists have claimed they found an atrophy in the cells in certain portions of the brain in cases of dementia praecox autopsied, but as most cases of dementia praecox live for years in a state of apathy without any mental activity, the atrophy of the brain cells is probably due to disuse. Until the pathologist can prove definite brain changes in cases coming to autopsy early in the disease, I shall continue to insist that whatever atrophy has been found in the brains is due to disuse of the mental processes and not to disease of the brain cells. As only 16 cases of dementia praecox were discharged as recovered during the year, and only 259 cases as improved, it proves conclusively that present

methods of treating this form of mental disease are lacking. I regret that the statistics do not give the type of dementia praecox of the 16 cases recovered or the length of their hospital residence. When I was in the Rochester State Hospital I was much surprised to discover that practically 50% of the permanent population of the hospital was diagnosed as dementia praecox. If this holds true for all the hospitals we can say that in 1913, 16,299 were cases of this type, and at \$200 *per capita*, and with an average hospital residence of 14.9 years, they will cost for their care \$48,651,120.00.

THE DEVELOPMENT OF A MENTAL DEFECTIVE BY VOCAL DRILL.

By WALTER B. SWIFT, M.D., BOSTON.

In Charge of Voice Clinic, Boston State Hospital, Psychopathic Department; Instructor in Neuropathology, Tufts Medical School.

ABSTRACT: AN ALMOST HOPELESS DEFECTIVE.—DRILLED FOR MONTHS.—FINALLY SHOWED UNEXPECTED MENTAL DEVELOPMENT.

We are all interested in individuals who are much changed mentally. We too often picture brain and mind as pretty stationary, rather fatalistic, fossilized crystallization. We all have some time in our lives been sized up by others and this imprinted picture enforced upon us years later, after our mental makeup, our constellation of inter-related mental reactions, has found new channels, new interests and new aims. Many children never grow up to their parents. I should prefer to be treated like what I may possibly be five years hence, rather than like what I was five years back. It would be nearer absolute truth—for what I am thinking now in vague form will be printed then. Some men's minds are ever enlarging as years go on. The environs they place themselves in enforce it. Such men can never be thought of as stationary characters. Such men can never be pictured again as we pictured them the last time we met. If you do, they feel confined, belittled, unappreciated. It is fair to approach them only with open interest, ever inquiring. What is new?

It was after a start, teeming with hopelessness and doubtful of what vocal drill would accomplish, but yet willing to try, that I was finally driven into the state of mind typified by the question—what new—at almost every visit of

the case, I am about to present. Thus unexpected, even weird, unprophesied and unheralded came advance after advance to the little mind under drill, until what may be called a new constellation of inter-related ideals and interests settled down as the indwelling spirit of a formerly rather comparatively blank mentality.

These generalizations will be cleared up and take forms in concrete pictures by the presentation of the case:—

CASE. William Morgan, boy, aged 11; American; school grade 3. Vocal record:—

Complaint. "Brought for voice examination."

Present Condition. Makes vague efforts at articulation, which strangers do not understand. He is understood at home and his teacher understands him in school.

Previous History. Measles and chicken pox. At 4 operation for "tongue-tie." No relief. Began school at 4, always backward, especially in arithmetic, which he seems unable to grasp. Up to age of 8 could say only a few words. Much improvement in last three years.

Family History. Father and mother living and well; maternal grandmother died at 35 of tuberculosis. One maternal uncle had convulsions as a child and his speech was indistinct. He died at 16. Paternal grandfather dead. Cause unknown. Paternal grandmother alive and well at 65.

Physical Examination. (By Dr. W. P. Lucas.) "Poorly developed and poorly nourished for 11 years. Face slightly asymmetrical. Otherwise a complete examination is negative. No physical defects to account for his speech defect or mental condition."

Psychological Examination. Binet, 4-5 years. To a fair degree educable. Diagnosis: Mental defective.

Vocal Examination. In general, voice is vague and indistinct and characterized by short, sudden, explosive replies. Often says "yes" quite irrelevantly.

Vowels comply pretty well to local standards.

Consonants: Explosives are good except "G." For "th" says "f"; for "r" gives a nasal twang.

Utterances show constant uninhibited imitation; almost an uncontrolled low speech reflex. For example, when asked to say peripatetic he says quickly "peptic," never dwelling with good execution upon details. "R" sometimes like "W." "S" and "th" very faulty. "D" and "S" often omitted.

Can be understood at home and by one teacher in school. Strangers cannot understand him.

Prognosis. Poor but worth trying.

Treatment. Given vocal exercises, breathing exercises and muscle gymnastics varying somewhat as time passed and different stages of development arose.

Continued for over eight months on an average of 1 to 2 hours daily.

At the end of this time the patient could pronounce all vowels correctly, enunciate all consonants perfectly when not in combination. He could say simple combinations of words and sentences and more difficult ones after some practice.

Besides these merely articulatory attainments he showed several lines of mental unfoldment as follows:—

After two months his teacher reported improvement in his reading in school. After three months parent reported he was making a stronger and

* No. 2 may be found in the BOSTON MED. AND SURG. JOURNAL, Oct. 7, 1913.

more continued effort in his home practice. Also is trying more to read words, understand pictures (as in newspapers) and understand what they mean.

After four months showed ability to learn a new poem in two days as well as he did his first poem in three weeks. After five months parent reported more interest in reading, a demonstration of more personal self-control, and better attention. Also has an increased interest in writing. After six months began to show improvement in speed of utterance. Arm movements during talking are less. During the eighth month showed a permanent forward advancement in mental powers, facial expression and interest,—shown in his reading the newspapers, drawing pictures, writing, and several other minor activities never shown before. Finally, he added to these changes a desire to tell stories at the table, such as describing an accident, or other occurrence he had seen in the street. After seeing acquaintances in the street, comes home and remarks on their dress, change of dress, etc. He also picks more words from the newspaper, spells them and asks their meaning, shows interest in the calendar, knows some of the months and wants to know the rest.

Discussion. To the thoughtful reader this case in a measure explains itself. It is a case of very dull, inactive mentality, acting with little initiative, poor concentration of attention, narrowed unintellectual mental processes—that by long vocal drill was developed out of all these qualities to a certain extent, and out of some of them to a very marked degree. The drill about tripled his mental horizon, his activities and interests. And all this within a year.

Treatment. The details of treatment I should prefer to reserve at this time as they are not yet crystallized in final form. Then, too, I should prefer to try them upon a larger number of other cases and reduce them to some sort of method or system before they are presented in final form. Results have been marked enough to warrant the report of this preliminary note. Elsewhere I plan to present this same case in detail, psychologically analyzed, and at that time the steps of vocal drill will be presented in their relation to the various steps of mental change, as are to be pictured in that analysis.

Summary. Defective mentality subjected to an eight months' intensive vocal drill, with the result that a remarkable and unexpected mental development followed, showing in new initiative, wider interests, an extended observation and other minor mental manifestations.

A TIME-SAVING METHOD FOR MULTIPLE SUGAR ANALYSES.

BY B. H. RAGLE, M.D., BOSTON.

THE performance of a qualitative test for sugar in the urine requires, to be sure, scarcely three minutes—but, where there are ten or twenty urines to be examined, the amount of

time consumed is really considerable. Time thus spent is wasted. With this in mind experiments were undertaken to examine simultaneously several urines qualitatively for sugar by utilizing a water bath with perforated top. Such a water bath, with a plate perforated for test tubes, is to be found in most laboratories. Either the round or rectangular type is suitable and may be obtained at any laboratory supply house.

If Benedict's Solution is used the directions are as follows: The water bath, filled one and one-half inches, is placed over a large flame. While the water is coming to a boil about 5 c.c. of the re-agent are introduced into the same number of test tubes as there are urines to be examined. A very handy way is to have the tubes in a rack, and the solution can be run into them from a bottle. Eight drops of urine are now put into each test tube and the tubes immediately transferred to the boiling water bath and left for two and one-half minutes. Within 30 seconds to one minute the urines containing 0.5 per cent. or more sugar will have reduced the copper and in two and one-half minutes any specimen with a pathological trace of dextrose will be positive.

The method is just as applicable to Fehling's qualitative test. After the preliminary proof that the Fehling solution is not reduced by boiling, the tests are carried out in the ordinary manner and placed in the boiling bath two or three minutes.

ADVANTAGES OF THIS METHOD.

1. Multiple qualitative tests for sugar may be made simultaneously.
2. Bumping is avoided.
3. Test tubes are not broken.

REPLY TO AN ARTICLE BY DR. O. D. PHELPS ON A "NOB OF THE FRENUM OF THE UPPER LIP."

BY JOHN W. FARLOW, M.D., BOSTON.

IN the BOSTON MEDICAL AND SURGICAL JOURNAL for September 9, 1915, there is an article by Dr. O. D. Phelps calling attention to the frequent occurrence of a nob of the frenum of the upper lip. From his observations he had come to the conclusion that these nobes were not of syphilitic origin, but he had been unable to find any reference to them in spite of a recent query in the *Journal of the American Medical Association*.

I have seen many instances of this nob or tab of the frenum and have called attention to it in my clinics and lectures. When the late Dr. Thomas Dwight, Professor of Anatomy in the Harvard Medical School, was writing his articles

for Piersol's Anatomy, he came to my clinic at the Boston Dispensary to examine the mouth and throat from a clinical point of view. I was able to show him a number of cases having the nob of the frenum.

In Piersol's Anatomy, 1907, page 1540, Prof. Dwight says: "There is a distinct frenum of mucous membrane passing from the anterior nasal spine to the middle of the upper lip. The free edge is often irregular and may have a nodular enlargement."

We saw no reason to consider them of specific or other pathological nature but merely as anatomic peculiarities, perhaps from irregularity of growth, as often occurs near a bony suture.

Book Reviews.

Practical Materia Medica and Prescription Writing. By OSCAR W. BETHEA, M.D., Ph.G., F.C.S. Philadelphia: F. A. Davis Company. London: Stanley Phillips. 1915.

The author has compiled in the first part of the work a very satisfactory résumé of the *Materia Medica*. Briefly and in succinct form, we have spread before us all articles of medicinal value, their form, solubilities and doses. Included in this are numerous prescriptions, containing the articles mentioned, which have been largely copied from well known works on clinical medicine and treatment, but all of these, unfortunately, partake to a certain extent of the "shot gun" variety. Even though substantiated by such noted authors as are quoted, we cannot fail to admire the modern teaching, of the simple prescription, with its three parts, which are supposed to heal, "*cito, certo et jucunde*." A short discussion on the limited amount of Latin needed in prescription writing follows, and while the author may be an admirable authority on pharmacy, his Latin does not comply with what the writer learned years ago in school and college. His translation of *Fiat* is "make thou," while the former literal translation was "let there be made."

His demonstration of the metric system and its employment in prescriptions is hardly consistent with the customs of the countries in which this system is employed exclusively. For instance, he objects to the use of the period between grams and fractions of grams, and insists upon the use of a perpendicular line. In Germany, from personal experience, prescriptions written in this way, were rejected by pharmacists and the period always insisted upon. It would seem to be equally necessary when dollars and cents are written, invariably to have the perpendicular line dividing the total and the fraction. His insistence upon the absent figures,

to the right of the period being replaced by zeros, is to be thoroughly commended.

The second part of the volume is really the more valuable. Here, we find a most common sense and practical demonstration of prescription writing. Every point, with reference to compatibility, arrangement, forms and administration, is carefully considered. Furthermore, with homely illustrations, he points out the errors which are every day committed by practically every practising physician, and in a series of illustrations, shows how a prescription should not be written and in the same page the errors of the former, by writing it in satisfactory form with reasons for the change. Still, his commendation of proprietary preparations will hardly impress the younger physician of the present day, when students of all first class medical colleges are taught, both by didactic lessons and by experience in the inspection and handling of drugs, to write for articles which will be not only effective in combination, but elegant in appearance and pleasant in taste.

Henry Phipps Institute for the Study, Treatment and Prevention of Tuberculosis. Tenth and Eleventh Reports. Philadelphia: Henry Phipps Institute. 1915.

These two recently published reports of the Henry Phipps Institute continue the work of that organization in publishing the results of its research. The tenth report, by Dr. C. M. Montgomery and Dr. E. A. Eckhardt, deals with pulmonary acoustic phenomena, being an investigation of some of the factors concerned in the origin and transmission of sounds heard over the lungs in health and in disease. Particular attention is devoted to the voice sounds, spoken and whispered, and to the respiratory or breath sounds. The work is illustrated by an admirable table of diagrams representing the operation in some of the pulmonary and pleural conditions of reflection and diffusion as the most important factors that diminish sounds on their way through the chest. The eleventh report, by Dr. Frank A. Craig, records a study of the housing and social conditions in selected districts in Philadelphia, with especial reference to the relation of these to the incidence and prevalence of tuberculosis. The number of houses investigated in this study was 1003 and the number of people living in these houses was 5812. The work is abundantly illustrated with tables, graphic charts, diagrams and full-page plates, and by a large folding map of the district of the city investigated. An appendix contains a reproduction of the charts used in collecting the data for the report. Both these reports are useful contributions to the literature of progress in the knowledge of tuberculosis.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, NOVEMBER 11, 1915

EDITORS.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.50 per year for all foreign countries belonging to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 125 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

WORK OF MASSACHUSETTS SOCIETY FOR MENTAL HYGIENE.

ATTENTION is called to the program of the approaching mental hygiene conference and exhibit, which is to be held in Boston on Wednesday, Thursday and Friday of next week, November 17, 18 and 19. The program is published in full on page 757 of this issue of the JOURNAL. This meeting and exhibit are designed to exemplify the work which is being done by the Massachusetts Society for Mental Hygiene in its activities for the prophylaxis of mental disease and to afford occasion for the discussion of problems connected with this work and hopefully for the advancement of knowledge in its conduct.

As a leading article in this issue of the JOURNAL, we also publish an address by Dr. Frankwood E. Williams, executive secretary of the Society for Mental Hygiene, on legislation

for the insane in Massachusetts with particular reference to the voluntary and temporary care laws. This address, originally delivered before the Bristol and Essex North District Medical Societies, will appear as publication No. 5 of the Society. The fourth of these publications was the annual discourse before the Massachusetts Medical Society in 1912, delivered by Dr. Walter E. Fernald of Waltham on "The Burden of Feeble-mindedness" and published in the issue of the JOURNAL for June 13, 1912 (Vol. clxvi, p. 911). In the issue of the JOURNAL for June 24, 1915 (Vol. clxxii, p. 933) we also published another article by Dr. Williams on "Psychopathic Hospitals and Prophylaxis." These three papers, though separated by some interval from one another, are indicative of the type of work encouraged by the Massachusetts Society for Mental Hygiene and of the research accomplished by the physicians engaged in its activities. There is an immense field for profitable investigation in the great domain of mental diseases and abnormalities. The attention of the profession is particularly called to the importance of this work in the hope of inviting the interest of general practitioners, as well as of specialists in nervous and mental disease, in the work of the Massachusetts Society for Mental Hygiene and in its coming conference and exhibit.

REPORT OF THE HARVARD UNIVERSITY SURGICAL UNIT.

IN another column of this issue of the JOURNAL we have the pleasure and privilege of publishing simultaneously with the *Harvard Alumni Bulletin*, the full text of the official report prepared by Dr. Greenough of the work done by the Harvard University Surgical Unit at the American Ambulance Hospital, Neuilly, Paris, France, during its period of service there from April 1 to July 1, 1915. The financial sponsor of the expedition, it will be remembered, was Mr. William Lindsey, whose loyal generosity made possible the performance of a work once so creditable to the University and so valuable to those engaged in it. In his letter transmitting this report to the President and Fellows of Harvard College, Dr. Harvey Cushing in behalf of the department of surgery, and whose charge the expedition was conducted, writes in part as follows of the report and the work which it chronicles:

"The story of the Ambulance is doubtless more or less well known to you; but, as is true of most of the non-partisan activities in which philanthropic Americans have engaged on the fringe of the European conflict, fitful gossip and the news columns have sometimes dimmed the lustre of what is really a great work. To this the American Ambulance has been no exception, but whatever misgivings on this score may have been raised in the mind of any member of our expedition before his departure, they were promptly dispelled on the inauguration of our actual work, which each of us was loth to leave at the expiration of his time.

"It was gratifying to feel that we were of assistance to the wounded who came under our care, and this after all was the purpose for which we were sent. We trust, furthermore, that the service rendered was of such quality as to be worthy of the University in whose name it was performed. As Dr. Greenough points out, the Medical School will profit materially through collections presented to us by the Ambulance Committee, which will make a notable addition to the Warren Museum.

"I think I may safely express the feeling of our contingent by the statement that in the event of a second invitation to take over a similar service, they would urge its acceptance by the University and if given leave of absence would themselves again gladly volunteer as applicants for the various positions."

Already the achievements of American medicine and surgery in the European war have elicited comments of approval and admiration from the profession of the several European nations. As the war continues, further opportunity for similar and more extended service by American physicians and surgeons will constantly arise. At the present time a third Harvard Surgical Unit is about to sail for Europe for a six months' service. American physicians are at present actively engaged in relief work in Belgium, England, France, Germany and Russia. Opportunities such as the present for experience in military medicine and surgery during war will probably not occur again during the lifetime of any now engaged in professional activity. Unfortunate though the occasion of these opportunities may be, they should promptly be accepted by American physicians, not merely for the personal benefit and experience which they may afford, but for the credit which they may reflect upon the American profession and for their service to the interests of humanity.

A RABELAISIAN MEDICAL COMEDY.

THERE was more than coincidence, there seemed appropriate intention, in the selection of the opening night of the recent Clinical Congress of Surgeons in Boston for the *première* of "The Man who Married a Dumb Wife." This delightful little curtain-raiser of Anatole France, played as a prodrome to Shaw's "Androcles," is an exquisite bit of medical farce-comedy done by a modern in the best manner of Molière. Moreover, not only does the story concern doctors, but it was originally told by a physician, Maitre François Rabelais, the cynic philosopher of the sixteenth century.

In his grotesque and flamboyant chronicle of "Gargantua and Pantagruel," that unique conglomerate standing in literature midway between Boccaccio's "Decameron" and Burton's "Anatomy of Melancholy," Rabelais records a joyful incident in the student days of one of his characters at the University of Montpellier. The following translation of this passage is taken from the version of Sir Thomas Urquhart:

"Welcome, in good faith, my dear master, welcome! It did me good to hear you talk, the Lord be praised for all. I do not remember to have seen you before now, since the last time that you acted at Montpellier with our ancient friends, Anthony Caporra, Guy Bourguier, Balthasar Noyer, Tolet, John Quentin, Francis Robinet, John Perdrier and Francis Rabelais, the moral comedy of him who had espoused a dumb wife.

" 'I was there,' quoth Ephistemon, 'The good, honest man, her husband, was very earnestly urgent to have the fillet of her tongue untied, and would needs have her speak by any means. At his desire some pains were taken on her, and partly by the industry of the physician, and partly by the expertness of the surgeon, the encliglotte which she had under her tongue being cut, she spoke, and spoke again; yea, within a few hours she spoke so loud, so much, so fiercely and so long, that her poor husband returned to the same physician for a receipt to make her hold her peace. "There are," quoth the physician, "many proper remedies in our art to make dumb women speak, but there are none that ever I could learn therein to make them silent. The only cure which I have found out is their husbands' deafness." The wretch became within a few weeks thereafter, by virtue of some drugs, charms of enchantments, which the physicians had prescribed unto him, so deaf that he could not have heard the thundering of 1900 cannon at a salvo. His wife, perceiving that indeed he was as deaf as a door-nail, and that her scolding was but in vain, sith that he heard her not, she grew stark mad.

"Then the doctor, asking for his fee, the husband answered that truly he was deaf, and so was not able to understand what the tenor of this demand might be. Whereupon the leech bedusted him with a little, I know not what, sort of powder, which rendered him a fool immediately, so great was the stupefying virtue of that strange kind of pulverized dose. Then did this fool of a husband and his mad wife join together, and, falling on the doctor and surgeon, did so scratch, bethwack, and bang them, that they were left half dead upon the place, so furious were the blows which they received. I never in all my lifetime laughed so much as at the acting of that buffoonery."

This incident, in which Chaucer would have rejoiced as keenly as did Rabelais, was the one selected by M. France as the basis of his play, and he has expanded it into an exquisite bit of comic characterization and satire in the fashion not of Rabelais, but of Molière at his best. In the physician, surgeon and apothecary who come to cure the dumb wife, one can see the counterparts of characters in "Le Médecin Malgré Lui" or "L'Amour Médecin." It was Molière's instinct to caricature and lampoon the medical profession of his time, just as he made fun of the clergy, the law and the scholastics, but always genially and without sarcasm. France has caught this manner to perfection and, in his subtle ridicule of the doctors, merely pokes fun at their obvious shams and bombast. Take, for instance, the praise of the physician, Maître Simon, which he puts into the mouth of the surgeon, Jean Maugier:

"Oh! qu'il faut être reconnaissant aux savants médecins qui, tels Maître Simon Colline, travaillent à nous conserver la santé et nous soignent dans nos maladies. Oh! qu'ils sont dignes de louanges et de bénédictions, ces bons médecins qui se conforment dans la pratique de leur profession aux règles d'une savante physique et d'une longue expérience."

Again, when Léonard, the husband of the dumb wife, queries whether an apothecary need also be present at the operation, Maître Simon replies, "Oui, Monsieur, et quiconque en doute ignore totalement les relations des organes entre eux et leur mutuelle dépendance." Finally, the three are gathered for the procedure, before and after which they drink copiously at the expense of Léonard. Fee-splitting and medical perquisites were the rule of those days. Later, when the dumb wife, become garrulous, has driven her husband to distraction, the consultants are again summoned to reverse the process,

which, however, Maître Simon declares impossible:

"Hélas, monsieur le juge, il n'est élixir, baume, magistère, opiat, onguent, emplâtre, topique, électuaire, panacée pour guérir chez la femme l'intempérance de la glotte. La thériaque et l'orviétan y seraient sans vertu, et toutes les herbes décrites par Dioscorides n'y opéreraient point."

The only alternative is deafness for the husband, and this, says Simon, may be produced in various ways:

"Maître Simon. La cophose ou surdité peut être obtenue de plusieurs manières. On la produit soit par l'otorrée, soit par les oreillons, soit par la sclérose de l'oreille, soit par l'otite, ou encore par l'ankylose des osselets. Mais ces divers moyens sont longs et douloureux."

Léonard. Je les repousse! . . . Je les repousse de toutes mes forces.

Maître Simon. Vous avez raison. Il vaut bien mieux obtenir la cophose par l'influence d'un certaine poudre blanche que j'ai dans ma trousse, et dont une pincée, introduite dans l'oreille, suffit pour vous rendre aussi sourd que le ciel dans ses jours de colère.

Léonard. Grand merci, Maître Simon Colline; gardez votre poudre. Je ne veux pas être sourd.

Maître Simon. Quoi, vous ne voulez pas être sourd? Quoi, vous rejetez la cophose? Vous fuyez la guérison que vous imploriez tout à l'heure? C'est un spectacle trop fréquent et bien fait pour porter la douleur dans l'âme d'un bon médecin, que celui du malade indocile qui repousse le remède salutaire. . . .

Maître Jean Maugier. . . . Se dérobe au soins qui soulageraient ses souffrances. . . .

Maître Seraphin. . . . Et refuse d'être guéri."

Two pages of chatter by Catherine, however, make Léonard change his mind and the powder is employed. Then the consultants are soundly beaten and bitten and the comedy closes with the rollicking horse play of which the mediaeval drama was so fond.

France is felicitous, too, not only in his characterization, but in some of his indirect medical comment. For instance, Maître Adam, who first counsels the operation on Catherine, comments as follows on the difference between deamutes who learn to speak and dumb persons who are not deaf.

"Les médecins, apothicaires et chirurgiens, s'ils parviennent à faire parler un sourd-muet, ce n'est jamais que d'une langue aussi sotte que son oreille. Il n'entend ni ce qu'on lui dit ni ce qu'il dit lui-même. Il en va tout autrement des muets qui entendent. C'est un jeu, par

un médecin, que de leur délier la langue. L'opération coûte si peu qu'on la fait journellement sur les petits chiens qui tardent à aboyer."

Evidently the training of deaf-mutes was known before the days of Froebel and Horace Mann.

There is, perhaps, little of twentieth century relevance in the farce of "Celui Qui Épousa une Femme Muette," but the spirit of its satire and of its human allusion are as genuine today as in the time of Rabelais or Molière.

MEDICAL NOTES.

THE WEEK'S DEATH RATE IN NEW YORK.—During the last week of Commissioner Goldwater's administration there were 1194 deaths in the city of New York, and a death rate of 10.73 per one thousand of the population, as compared with 1134 deaths and a rate of 10.60 in the corresponding week of 1914, an increase of 60 deaths and of .13 of a point in the rate. According to the Health Department's statistician, there was a decrease of 50 per cent. in the death rate from diphtheria and croup, and an increase of about 10 per cent. in the acute respiratory diseases. The mortality from the remaining causes was about the same as that of last year.

Viewed from the point of age grouping, the deaths of children under five was considerably below that of the same week last year, while that of persons 65 years of age and over was considerably higher, the one almost counterbalancing the other.

The death rate from the first of January to date was 13.18 per one thousand of the population, as compared with a rate of 13.59 during the corresponding period in 1915, a decrease of .41 of a point.

GIFTS IN MEMORY OF PHYSICIANS FOR MEDICAL EDUCATION.—In his recent annual report, the president of Western Reserve University announces the gift of a sum of \$40,000, for the endowment of the medical school of the University, to be established as a fund in the name of the late Dr. Hunter H. Powell, who gave his life to the service of the school. President Thwing also suggests the establishment of a similar special fund in memory of the late Dr. Dudley P. Allen, the income to be used "for research in the science of surgery or for the support of its practice."

NATIONAL COMMITTEE FOR THE PREVENTION OF BLINDNESS.—The annual meeting of the National Committee for the Prevention of Blindness was held at the New York Academy of Medicine on Thursday of last week, November 4, under the presidency of the Honorable Joseph

H. Choate. Addresses were delivered by the Honorable William H. Taft and Dr. George E. DeSchweinitz, professor of ophthalmology in the University of Pennsylvania.

NATIONAL SOCIETY OF KEEP-WELLS.—In the issue of the *Washington Star* for October 27, is reported the organization in that city of a new lay society denominated the National Society of Keep-Wells. This society is organized for the purpose of holding lay meetings to be addressed by physicians on topics of hygiene and preventive medicine.

REGULATION OF THE PRACTICE OF MEDICINE.—The medico-legal bureau of the American Medical Association has recently compiled a digest of the case law on the statutory regulation of the practice of medicine which will be issued for the benefit of the legal and medical professions, of legislators and of the public.

MARRIAGE OF TUBERCULATES.—In the weekly report of the United States Public Health Service for Oct. 22 appears the following statement of a recent judicial decision annulling the marriage of a person who concealed the fact that he was suffering from tuberculosis:

"The courts have held in a number of instances that the marriage of a person suffering from a venereal disease might be annulled at the instance of the other party to the marriage when the existence of the disease had been concealed. The Supreme Court of the State of New York, in *Sobol vs. Sobol* (p. 3175 of this issue of the Public Health Reports) carries this legal principle one step farther.

"The defendant (the husband) had been treated for tuberculosis and knew that he was suffering from the disease. He concealed this fact from his fiancée, and explained certain symptoms by saying that he was suffering from a cold. After the marriage his wife discovered the nature of his illness and brought suit to annul the marriage. No issue resulted from the union.

"The court decided that, in view of the possible serious consequences of such a marriage to the wife, to the children if any should be born, and to the community, the marriage contract should be annulled. The legal basis of the decision was the fraud of the defendant in concealing and misrepresenting the condition of his health."

PREVALENCE OF MENINGITIS, POLIOMYELITIS AND TYPHOID FEVER.—The weekly report of the United States Public Health Service for October 22, states that during the month of September, 1915, there were in Maryland six cases of cerebro-spinal meningitis, seven of poliomyelitis and 609 of typhoid fever. During the same period there were in Massachusetts five cases of

meningitis, sixteen of poliomyelitis and 322 of typhoid. There were 274 cases of typhoid fever in New Jersey.

APPOINTMENT OF DR. HAVEN EMERSON.—Dr. Haven Emerson, formerly Deputy Commissioner and Sanitary Superintendent, will succeed Dr. S. S. Goldwater as Commissioner of Health of New York City. Dr. Emerson is well-known as a capable and efficient public health administrator and will, no doubt, continue the work and accomplishment of this important department in a manner commensurate with its opportunities and necessities. An address which Dr. Emerson delivered before the Harvard Medical Alumni Association on "The Relation of the Medical Profession to Preventive Medicine" appears in the *JOURNAL* of October 21, 1915. Of the work of Dr. Goldwater, editorial comment was made by the *JOURNAL* at the time of the publication of Dr. Goldwater's address to the Boston Dispensary on "Dispensaries: A Growing Factor in Curative and Preventive Medicine" (April 29, 1915, Vol. clxxii, No. 17).

SOURCE OF FOOT AND MOUTH DISEASE.—On November 2, the United States Department of Agriculture issued at Washington an official statement regarding the recent reoccurrence of foot and mouth disease in Illinois. This outbreak has been traced to a supply of anti-hog cholera serum prepared from the blood of hogs infected with foot and mouth disease, but showing no symptoms at the time. The serum was tested before being used but no evidence of contamination was found. Tests subsequent to the reappearance of the epizootic, however, show that the serum was infected. The Department makes the following statement relative to the control of the manufacture of this serum.

"The problem of producing serum which will be effective in controlling hog cholera and at the same time will be absolutely safe in general use is complicated by the fact that the Department of Agriculture has no authority over serum plants which dispose of their products exclusively in the State in which they are manufactured. Such establishments are amenable alone to State law and regulation. The virus act confers no authority on the Department to guarantee or certify any commercial serum, nor does it provide for a continuous examination and inspection of serum establishments, such as the meat inspection law provides for packing houses. The Department can control only serums and analogous products in interstate commerce when there is evidence that they are contaminated, dangerous or worthless, or when the manufacturer is not licensed to engage in such interstate business. The virus act was passed about two years ago, and within the short time intervening between its passage and the outbreak in 1914, and with the facilities available, the Department extended its inspection over serum plants just as far as the law and circumstances permitted. There were in October, 1914, about ninety serum

plants holding Federal licenses, located at widely separated points in the United States. This condition rendered continuous inspection very expensive and impossible with the funds legally available for the purpose."

AMERICAN ASSOCIATION FOR STUDY AND PREVENTION OF INFANT MORTALITY.—The sixth annual meeting of the American Association for Study and Prevention of Infant Mortality is to be held in Philadelphia, November 10-12, 1915.

The subjects to be discussed include:

Eugenics.

Effect of the economic standing of the family on infant mortality.

Infant welfare nursing in small cities, towns and rural districts.

Institutional mortality.

Midwifery conditions.

Treatment and prevention of respiratory diseases.

Mr. Homer Folks of New York is president of the Association, and Dr. S. McC. Hamill of Philadelphia, president-elect for 1916. Dr. Joseph S. Neff, 801 Weightman Building, Philadelphia, is chairman of the Committee on Local Arrangements.

The sessions will be under the chairmanship of the following:

Eugenics—Dr. Wm. F. Snow, New York City
Pediatrics—Dr. Charles A. Fife, Philadelphia
Obstetrics—Dr. Mary Sherwood, Baltimore.

Economic Aspects of Infant Welfare—Mr. Sherman Kingsley, Chicago.

Nursing and Social Work—Miss Ella Phillip Crandall, New York City.

The session on Economic Aspects of Infant Welfare will be a joint one with the Philadelphia County Medical Society and will be held at the College of Physicians. All other sessions will take place at the Bellevue-Stratford Hotel.

The provisional program for this meeting contains promise of a number of interesting and important papers. Among the Massachusetts physicians who are to present addresses are Dr. John Lovett Morse and Dr. James Lincoln Huntington of Boston. A more extended account of this conference on infant mortality with comment on certain aspects of the problems which it involves will appear in next week's issue of the *JOURNAL*.

SPECULATION IN DRUGS.—In continuance of the comment on the increased cost of drugs and of the factor of speculation in the production of this increase, may be quoted the following item from a recent issue of the *New York Commercial*.

"The unprecedented upheaval in drug and chemical market conditions growing out of the derangement of former sources of supply in Europe, Russia, Asia, Turkey, Egypt, Japan and China and the Far East, has resulted in net advances ranging anywhere from ten to more than

one hundred per cent. since June 1, a period of less than six months.

"If we accept the explanations of leading handlers of drug and chemical products the cause of these conditions lies almost wholly in the curtailment of foreign drug supplies. So diversified is the business in drugs, chemicals and dye materials and allied products, however, that no single interest or even group of interests is in a position to offer satisfactory explanations justifying the present extraordinary position of the market.

"Were an investigation to be conducted the ultimate findings would no doubt be that, notwithstanding the rigid restrictions placed upon outgo by American manufacturers and first hands, of the most important products, speculators have succeeded in corraling great quantities which have been purchased by those belligerents in Europe still in position to receive shipments from America at fabulous prices.

"Quinine occupies the centre of the stage to-day, the price having advanced from a normal figure of around 28 cents an ounce to \$2.25 an ounce. The domestic production of this article is only one-half of what the annual imports of foreign sulphate amount to. It is said by authorities that more than 500,000 ounces of quinine have been exported to Europe since the commencement of the European war. The action of the domestic makers in restricting the outgo to their regular customers to their bare pro rata share of what remains in the hands of the former interests is commendable, but is tantamount to locking the stable door after the horse has made his escape.

"Exceptional conditions have, of course, appeared in a great number of drug products which have justified reasonable advances. The efforts at domestic production of aniline oil, beta naphthol, para-nitra aniline, carbolic acid and a great many other chemicals which were formerly obtained almost exclusively from Europe have attracted much attention. Speculators have seized the supplies of these products as well as many other stable articles, however, and in the wild scramble for dollars the industrious chemist who has been endeavoring to supply the much-needed trade wants of today has been relegated to oblivion."

Another evil of this situation is that a spurious spirin, consisting of calcium, starch, alum, cream of tartar, citric acid, and milk sugar, has been produced and is being marketed; likewise a balsalvarsan equally fraudulent. The United States Department of Agriculture has issued a warning against these preparations.

AWARD OF NOBEL PRIZE.—Report from Stockholm on October 30 announces that the Nobel prize in medicine for 1914 has been awarded to Dr. Robert Parany of the University of Vienna for his work in physiology and pathology. Previous awards of the Nobel Prize in medicine and physiology have been made as follows:

1901, Dr. Emil von Behring, for his work on sero-therapy in diphtheria; 1902, Dr. Ronald Ross, for his work on malaria; 1903, Dr. Niels R. Finsen, for his work on the photo-therapy of lupus; 1904, Dr. Ivan Petrowitch Pawlow, for his work on the physiology of digestion; 1905, Dr. Robert Koch, for his work on tuberculosis; 1906, Dr. Camillo Golgi and Dr. Santiago Ramon y Cajal, for their work on the anatomy of the nervous system; 1907, Dr. Charles Louis Alphonse Laveran, for his work on the protozoa; 1908, Dr. Paul Ehrlich and Dr. Elie Metchnikoff, for their work on immunity; 1909, Dr. Theodor Kocher, for his work on the physiology, pathology and surgery of the thyroid gland; 1910, Dr. Albrecht Kessel, for his work on proteid substances; 1911, Dr. Allvar Gullstrand, for his work on optics; 1912, Dr. Alexis Carrel, for his work on the suture of vessels and the transplantation of vessels and organs; 1913, Dr. Charles Richet, for his work on anaphylaxis. The award of the prize for 1915 will be reserved until 1916.

EUROPEAN WAR NOTES.

AMERICAN RED CROSS UNIT IN GERMANY.—Report from Rome states that on October 29, Dr. B. W. Caldwell and other American Red Cross surgeons, passed through that city on their way to Germany through Switzerland. The unit which they composed is to undertake the medical care of Russian prisoners in Germany.

RETURN OF DR. BEAL.—Report from New York states that on October 31, Dr. Howard W. Beal of Worcester, Mass., landed in that city aboard the steamer *Rotterdam* from Falmouth to England. For the first fourteen months of the war Dr. Beal has been in the service of the American Red Cross in England and has had charge of the American Women's war hospital at Paignton, Devonshire. At the close of his service there Dr. Beal was awarded the British Red Cross medal and was received by a committee of thirty prominent British physicians including Sir William Osler, Sir Alfred Keough, medical director-general of the British army and Sir Arthur May, medical director-general of the British navy.

CHOLERA IN AUSTRIA HUNGARY AND GERMANY.—During the week ended August 14, there were in Austria 3775 cases of Asiatic cholera with 2008 deaths, the majority being among the civil population. Of these cases 3532 with 1979 deaths occurred in Galicia. In Hungary during the week ended August 15 there were 388 cases of cholera with 242 deaths. During the week ended September 11, 1915, there were only three cases of cholera in Germany all among civilians. There were isolated sporadic cases of the disease among prisoners in detention camps at Bromberg, Frankfort, Magdeburg, Marienwerder, Oppeln and Pottsdam.

WORK OF THE LAFAYETTE FUND.—The work of the Lafayette Fund, one of the principal New England funds for European war relief, has consisted in the distribution among soldiers at the front of kit bags containing surgical dressing materials and other necessities valuable to soldiers in action or in the trenches. Over 25,000 of these kits have already been distributed. The chairman of the Boston committee of this fund has recently received the following appreciative letter from the American Relief Clearing House in Paris, relative to the work done by this fund.

"We think it would be interesting to you to know that we have recently passed the number of 25,000 Lafayette kits, which we have distributed to the soldiers at the front in your name. We are sending this information next week to the Paris papers, telling the French people of your generosity and of the remarkably useful selection of things which you have chosen to put in these Lafayette kits, which, without doubt, have proven to be the best hit of the war in their way.

"We should like to repeat to you the truly genuine appreciation and gratefulness of every soldier who receives one of these kits. They all demand them—every man in the army would like a Lafayette kit, and soldiers, when they return to Paris for their few days' vacation from time to time, are constantly beseeching us for one of these famous gifts. With very rare exceptions, however, we never distribute kits in Paris. We take the greatest pains and the greatest care in our distribution, and no soldier at the front who makes application can have one unless his application has been countersigned by at least his captain. We believe, as we have written elsewhere to you, that one of the most efficient methods, and one that would please you most, is the personal distribution of these kits to those soldiers of whom we have some knowledge. We are, therefore, preparing daily about eighty individual kits at our warehouse, which we send off the following morning.

"It may be interesting to you to know that the regulations call for all kits and other small packages to be sewn up in white cloth with the name written thereon in indelible ink. It is a great pleasure for us, however, to take this extra care for these much-appreciated gifts and we take great pride and great satisfaction in distributing them in your name to those who find so much pleasure in receiving them."

All checks and money orders should be made payable to Lafayette Fund and mailed to the Old Colony Trust Company, 17 Court Street, Boston.

WAR RELIEF FUNDS.—On Nov. 6 the totals of the principal New England relief funds for the European War reached the following amounts:

Belgian Fund, \$277,704.36; American Ambulance, \$66,897.00; British Fund, \$23,450.89; French Fund, \$21,654.82; St. George's Fund, \$12,085.51; La Fayette Fund, \$11,013.99; Italian Fund, \$10,768.69; Allied Fund, \$10,307.00; Surgical Dressing Fund, \$3904.00.

BOSTON AND NEW ENGLAND.

BOSTON DEATH-RATE LOWER.—During the week ending October 30 there were 180 deaths reported with a rate of 12.90 per 1000 of population as compared with 213 deaths and a rate of 15.43 for the corresponding week of last year.

The principal differences were in tuberculosis which numbered 16 deaths for the week against 30 last year, and in diarrhea and enteritis under 2 years which numbered 8 deaths for the week against 21 last year.

For the same week there were 34 deaths under 1 year of age as compared with 43 last year. Of these 24, 3 were less than one day old and 6 less than 1 week; 10 died in hospitals; 5 died of diarrhea and enteritis in hospitals and 3 of the same disease at home.

The total number of 1915 deaths reported up to noon of October 21 is 9821 against 9756 in the same period last year. Inasmuch as Boston's population is about 8000 greater than last year these totals indicate a slightly lower rate this year than last.

Deaths under 1 year reported from Jan. 2 to Oct. 30 number 1671 against 1666 for the corresponding period last year.

SUMMARY OF VITAL STATISTICS.—Boston had 793 deaths reported in the four weeks ending October 30, against 841 in the corresponding period last year, and a death-rate of 14.20 against 15.23.

Reported deaths of non-residents numbered 116 against 103 last year.

Of deaths from reportable diseases the principal decreases were:

Tuberculosis (all forms)	26
Diphtheria	9
Scarlet fever	4

and the principal increase was:

Whooping cough	10
----------------------	----

Other important differences were as follows:

DECREASES.	
Organic diseases of heart, endocarditis and nephritis	29
Diarrhea and enteritis (under 2 years) ..	18
Premature birth	14
Cancer	8
Diarrhea and enteritis (2 years and over) ..	8

INCREASES.	
"Other causes"	50
Violent	5
Pneumonia	5

There were 17 less deaths under 1 year, 418 under 5 years and 39 less over 60.

Deaths under 1 year reported from Jan. 20 to Oct. 30 number 1671 against 1666 for the corresponding period last year.

The total number of 1915 deaths reported up to noon, Oct. 31 is 9821 against 9756 in the same period last year.

Mortality Report for the four weeks and the same period in 1914:

	1915	1914
Total deaths	793	841
Non-residents	116	103
Rate	14.20	15.23
Corrected rate (Non-residents deducted)	9.10	10.03
Deaths under 1 year	149	166

HOSPITAL BEQUESTS.—The will of the late Warren M. Hill of Boston, which was filed at the local probate office on Nov. 1, contains a bequest of \$2500 to the Woman's Charity Hospital, Roxbury.

The will of the late Luther Hills Pierce of Chicago, who was born at Bangor, Me., in 1837, contains a bequest of \$100,000 to the Eastern Maine General Hospital, located at Bangor.

LONG ISLAND HOSPITAL.—The eighteenth annual report of the Boston Infirmary Department for the year ending January 31, 1915, states that the average population at Long Island has been 1000, an increase of 91 over the previous year. The cost per capita in the hospital was \$5.99. The new buildings begun in 1913 are completed and occupied. The kitchen building and bakery have been equipped with the most approved machinery and appliances and the men's dormitory has been rebuilt to form an administrative center for the entire group of buildings. Funds have been appropriated for the erection of a nurses' home with accommodations for about eighty nurses and two ward buildings with a capacity of fifty-four beds each. The visiting medical staff of the hospital call attention to the pressing need of laboratory facilities. They state that the opportunities at the Long Island institution are exceptional for men of earnestness and enthusiasm, that a pathological and chemical laboratory equipped in the most modern way would serve as a center for research and for the routine work of the hospital. It is not to be doubted, were such laboratories established, that the hospital would greatly benefit, not only as a most adequate means of training young men for the practice of medicine but also as a means to the more adequate and scientific treatment of its patients.

MASSACHUSETTS SOCIETY FOR MENTAL HYGIENE.—At a recent meeting of the Massachusetts Society for Mental Hygiene, Professor William H. Burnham, of Clark University, was elected president to complete the unexpired term of the late Judge Harvey H. Baker. Other officers of the Society for the ensuing year were elected as follows: Dr. Walter E. Fernald, vice-president; Dr. Charles E. Thompson, Gardner, secretary; John Koren, Boston, treasurer; Dr. Frankwood E. Williams, Boston, executive secretary. Members of the executive committee of the board of directors are Dr. James J. Putnam, Boston; Dr. Alfred E. P. Rockwell, Worcester;

Miss Edith N. Barleigh, Boston; Dr. Henry R. Stedman, Brookline, and Prof. Robert M. Yerkes, Cambridge.

NEW IDEAS IN THE CARE OF THE INSANE.—Another record of the therapeutic value of work in the care of the insane is found in the October bulletin of the Massachusetts State Board of Insanity. The superintendent of Danvers State Hospital reports the success of an experiment with a group of patients who were disturbed, restless and occasionally violent. About seventy strong, able-bodied inmates of this class were employed during the summer in reclaiming waste land along the Ipswich River. From three to four acres have already been made available for agricultural purposes and the effects of such systematic occupation on the part of the patients has been very encouraging. Even refractory cases who, by reason of violent and troublesome conduct, had led the vacant, fruitless lives of custodial cases, have become quieter and more amenable to order and hospital rules under the moral reaction of definite accomplishment.

In this connection it is interesting to note an experiment which is being tried in Germany. At Bedburg, in that country, a garden city for over 2000 lunatics has been established. German doctors have recognized that the method of keeping lunatics in asylums is a mistake. The best way to cure them, they say, is to give them as much freedom and open air as possible. The garden city of Bedburg consists of 36 large houses, each capable of accommodating 80 to 100 patients. A large farm has been established and stocked with cattle and horses. Everything that is necessary for a small town, in fact, is to be found in the newest of garden cities. It has even a theatre. The lunatics are free to walk about and to amuse themselves just as they like. They willingly work on the farm, and the women cook as eagerly and cheerfully for the others as though they were living in their own homes, free from insanity. The total cost of this ideal asylum was \$2,000,000.

Correspondence.

TREATMENT OF INSANE CRIMINALS.

NEW YORK, October 28, 1915.

Mr. Editor: Your editorial in the issue of October 21st, 1915, on "Re-education of Demented Patients in Hospitals for the Insane," should have very wide publicity and work great good to many sufferers.

What you write is unquestionably true of hospitals for the insane who are not criminals, but how much worse is it for those who are thus classified.

I am familiar with both, as far as may be. In the latter, there are no kindly and intelligent visitors, who are appreciative of the patients' needs and who are able and willing to aid them by visiting and giving games, or instructions, which would be of great service in helping improve their woe-begone condition. During many years, and while prisons and

prisoners sadly required reform and improvement. I did what I could. To-day, my mind and heart go out a great deal more to the lot of the criminal insane, and I urge most strongly the great need in the directions so well emphasized by you.

Could you not direct special attention to this urgent need by the daily press, so that not only in Massachusetts, but also in New York and other states, more will be done than is now being effected. Not long since, I had this in mind and wrote to the warden of one of our large state hospitals for the criminal insane, to enquire if I could not be the means of acquiring games of different kinds for the prisoners in his charge? The reply came to me, that the supply was already large, or sufficient, and that my efforts in this direction were not, in his judgment, needed. Despite this statement, I can not agree with him and I am very glad to read an editorial like yours, which brings attention to what I still consider a crying want.

In New York to-day, there is some foolish doing alongside of a great deal that is beneficent and praiseworthy in the management of sane criminals, but for the insane criminals there is a great dearth of doing, which I greatly deplore.

May I hope to awaken among those who have knowledge and power, the desire further to know and follow what is now being done at the State Psychopathic Institute, Illinois, under the supervision of Dr. S. H. Clark, physician to this hospital.

It would be well if everyone should obtain and carefully read Dr. Clark's report in connection with your admirable editorial. At least, it would be very desirable for all those who have power, willingness and initiative, to do immense good to a large number of great and neglected sufferers.

To the prominent specialists in neurology, to the psychiatrists and to the wardens of state hospitals for insane criminals, I specially send this most sincere appeal.

BEVERLEY ROBINSON, M.D.

AN AMERICAN MEDICAL STUDENT IN SCOTLAND.

(From Our Special Correspondent.)

EDINBURGH, October 18, 1915.

Mr. Editor: I have been in Edinburgh working in the laboratories for almost two months now. The fall term at the University and the Royal Colleges of Edinburgh has just begun and a remnant of the original student body has returned. At the college where girls are allowed to study medicine there is a record enrollment and report has it that an unprecedented number of girls have entered for medicine in London also.

At the university here the large proportion of medical students are East Indians and South Africans now. There is no medical course given in British South Africa. The result is that many come across the water, most of them to Edinburgh. Very few of either Indians or South Africans have enlisted. When war broke out the Scottish students who were, many of them, already members of the artillery, enlisted in great numbers. This fall many of the more advanced men, who went off as medical assistants on submarines or destroyers, have reappeared in order to finish their courses. Commissions are held open to them as there is a considerable shortage of qualified men in both the army and navy. In fact, the army just recently sent out a call for 2500 more doctors.

A student who is staying in the same lodging house with me went to Belgium at the beginning of the war under Doctor Soutar. Later, although he had never obtained his degree, he was placed on a cruiser and took charge of the medical work there, having two destroyers also under his supervision. Now that he has returned he will take his final examinations in December. The authorities seem quite willing that the men should push through as quickly as possible.

It is interesting to hear the returned students talking of their classmates. "Such-and-such a man is wounded, in a French hospital; his room-mate is reported among the missing. Another has been sent home from the Dardanelles, sick with dysentery. Many have come back for that reason." Judging from the stories of these men, life in the Dardanelles must be more terrible than in France. The troops are never out of range of the Turkish guns. The beach seems to be the most dangerous place of all. Wounded are carried out, as best they can be, to hospital ships. They get no bread, only hard-tack, for food, and water must be brought great distances by boat. Their turns in the trenches have been sometimes as long as three weeks. During the past summer the flies, fleas and heat have been awful, and lately dysentery has arrayed itself on the side of their enemies.

On the whole, Edinburgh is the most warlike city I have visited in Great Britain. The Scotsmen tell you with great pride that Scotland has outstripped England, Ireland and Wales in recruiting. From every signboard and vacant window Lord Kitchener's posters glare upon the men who have not yet gone, and appeal to them in a hundred different ways to come along with "the boys at the front." Any evening that one may walk along Prince's street he is sure to find a recruiting meeting and, if he is a young man, people turn around and give him the "why aren't you in kahlki?" stare. One trolley car is set aside for recruiting. It passes along the different lines and extends a continual invitation to men to come aboard and enroll themselves with His Majesty's forces.

In the afternoons we often go out to play tennis and as we pass along the street with racquets and things, the little boys cry out after us—"shirkers! shirkers!" It makes even me, who am fortunate enough to be an American, feel very uncomfortable. I have almost grown used to being angrily stared at by women on the street cars. But it seems as though it would require more courage for a British subject to stay at home and face Scottish scorn than to enlist and face German artillery.

Conscription is a much debated topic. Most people with whom one talks favor it, but it seems doubtful now whether it will come for some time, if at all. The national registration slips are said to have been distributed to the various recruiting officers and it is expected that a thorough canvass of all men eligible for service will soon begin. But, notwithstanding the pressure of public sentiment, no city of Great Britain presents anything like the deserted appearance of a French city. In the Highlands of Scotland, I have been told, there are many small towns which have left to them not one able-bodied man. Conscription would, however, bring into the ranks very many men from the larger cities.

Sincerely yours,

W. G. F.

DRINKING WITH MEALS.

Boston, October 27, 1915.

Mr. Editor: The Massachusetts Anti-Tuberculosis League has been asked to prepare a legislative bill to prohibit saloon keepers from giving food to their patrons free of charge. Facts have been presented to us, showing the unclean condition of the utensils used on the food counter in the saloons and the probability that those eating food from these dishes are in danger of contracting tuberculosis. In talking this matter over with several physicians, the theory was advanced that it is much better for a person to take alcoholic beverages after eating than on an empty stomach. Connecticut, however, recently passed a law prohibiting the giving of free food to patrons of saloons. Will some of the medical readers of the JOURNAL be willing to send us their opinion in regard to this matter?

Yours very truly,

S. H. STONE, Secretary.

PROGRAM, MENTAL HYGIENE CONFERENCE AND EXHIBIT.

Ford and Kingsley Halls, Ford Building, 15 Ashburton Place, Boston, Mass., November 17, 18, 19, 1915.

Wednesday evening, November 17, 8 P.M.

Presiding officer, William H. Burnham, Ph. D., Professor of pedagogy and school hygiene, Clark University, Worcester.

What Research Has Accomplished for Mental Hygiene.
Dr. Elmer E. Southard, Director, Psychopathic Hospital, Boston.

The Meaning of the Mental Hygiene Movement.
Dr. William A. White, Superintendent, Government Hospital for the Insane, Washington, D. C.

Thursday afternoon, November 18, 3 P.M.

Presiding officer, Mrs. George A. Perkins, President, Massachusetts Federation of Women's Clubs, Boston, Social Service in State Hospitals.

Miss Mary C. Jarrett, Chief of the Social Service, Psychopathic Hospital, Boston.
Community Value of State Hospital Out-Patient Departments.

Dr. John B. MacDonald, Assistant Superintendent, Danvers State Hospital, Hathorne.
Occupation Therapy in State Hospitals.

Miss Emily L. Haines, Supervisor of Industries, Massachusetts State Board of Insanity.
What Shall be the Attitude of the Public Towards the Recovered Insane Patient?

Dr. Harry C. Solomon, Assistant Physician, Psychopathic Hospital, Boston.
After-Care of Mental Patients.

Dr. Henry P. Frost, Superintendent, Boston State Hospital, Dorchester Centre.

Thursday evening, November 18, 8 P.M.

Presiding officer, Dr. Allan J. McLaughlin, Massachusetts Commissioner of Health, Boston.
Preventable Forms of Mental Disease and How to Prevent Them.

Dr. E. Stauley Abbot, Pathologist, McLean Hospital, Waverley.
Rational Care of the Inebriate.

Dr. Irwin H. Neff, Superintendent, Norfolk State Hospital, Pondville.

What Recent Investigations Have Shown as to the Relation of Mental Disease and Crime.

Dr. A. Warren Stearns, Assistant to the Massachusetts State Board of Insanity, Boston.

The Relation of Alcohol to Mental Disease.
Dr. A. J. Rosanoff, Kings Park State Hospital, Kings Park, N. Y.

The Relation of Syphilis to Mental Diseases.
Dr. Samuel T. Orton, Pathologist, Pennsylvania Hospital, Philadelphia, Pa.

Friday Afternoon, November 19, 3 P.M. Annual Meeting of the Society.

Prof. William H. Burnham, President, Massachusetts Society for Mental Hygiene, presiding.
Dr. Charles E. Thompson, Secretary.

Report of the Secretary.
Report of the Treasurer.

Report of the Executive Secretary.

Symposium: Mental Diseases: Methods and Program.

Dr. Walter Channing, Brookline.

Dr. Everett Flood, Monson.

Dr. George W. Gay, Boston.

Dr. L. Vernon Briggs, Boston.

Dr. John A. Houston, Northampton.

Dr. Herbert E. Howard, Brookline.

Mrs. William H. Lothrop, Brookline.

Dr. Ernest V. Scribner, Worcester.

Robert A. Woods, Boston.

Mrs. Ada E. Sheffield, Cambridge.

Dr. George T. Tuttle, Waltham.

Dr. Henry P. Walcott, Boston.

Election of Directors.

Terms expire 1915.

Hon. Henry V. Cunningham	Mr. Seward W. Jones.
Henry Ehrlich, M.D.	John M. Merriam, Esq.
Everett Flood, M.D.	Bishop William Lawrence.
George W. Gay, M.D.	Hon. Frank L. Randall.
Herbert J. Hall, M.D.	Walter Channing, M.D.
John A. Houston, M.D.	Hon. W. Murray Crane.

Vacancies.

Hon. Harvey H. Baker, deceased, Term expires, 1916.
J. E. A. Adams, M.D., deceased, Term expires, 1916.

Friday evening, November 19, 8 P.M.

Presiding officer, Dr. Franklin B. Dyer, Superintendent of Schools, Boston.

Mental Hygiene of Children.

William H. Burnham, Ph. D., Professor of Pedagogy and School Hygiene, Clark University, Worcester.

Mental Preparedness.

Dr. James J. Putnam, Professor Emeritus of Diseases of the Nervous System, Harvard University.

Heredity and Mental Disease.

Dr. Henry H. Goddard, Director, Vineland Training School, Vineland, N. J.

CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR THE FOUR WEEKS ENDING OCT. 23, 1915.

September 26, Surgeon W. M. Garton, from *Solace* to Fleet Surgeon, Atlantic Reserve Fleet.

Surgeon C. G. Smith, detached, Naval Hospital, New York, to Bureau of Medicine and Surgery, Navy Department, Washington, D. C.

Surgeon C. M. Oman, to Naval Hospital, New York.

Surgeon P. A. Asserson, detached, *Wisconsin* to home, wait orders.

Surgeon E. M. Blackwell, detached, Bureau of Medicine and Surgery, Navy Department, to *Solace*.

P. A. Surgeon W. J. Biddick, from Naval Hospital, Norfolk, to *Neptune*.

P. A. Surgeon P. E. Garrison, from *Solace* to *Washington*.

Surgeon W. D. Owens, from *Utah* to Training Station, Newport, R. I.

September 29, P. A. Surgeon A. E. Lee, Temporary duty, Navy Recruiting Station, Richmond, Va.

P. A. Surgeon G. R. W. French, from Naval Hospital, New York, to temporary duty at Navy Yard, New York.

Asst. Surgeon B. C. Willis, M.R.C., detached, Naval Recruiting Station, Richmond, Va.

September 30, P. A. Surgeon W. J. Zalesky, from Cavite Station, to *Saratoga*.

P. A. Surgeon, from Canacao Hospital, to *Wilmington*.

October 2, P. A. Surgeon W. L. Irvine, from Training Station, Newport, R. I., to *Chester*.

P. A. Surgeon H. I. Brown, from *Chester* to home, wait orders.

Asst. Surgeons, L. F. Drum, Paul Richmond, M.R.C., to Naval Medical School, Washington, D. C.

October 5, Asst. Surgeon S. D. Hart, from Newport Hospital to Newport Training Station.

October 12, P. A. Surgeon H. L. Smith, to Navy Yard, Boston, Mass.

P. A. Surgeon M. H. Ames, from Navy Yard, Boston, to *Georgia*.

October 12, P. A. Surgeon A. R. Clifford, from Naval Medical School, Washington, D. C., to U. S. S. *Washington*.

October 16, P. A. Surgeon G. D. Hale, from *Ohio* to *North Dakota*.

P. A. Surgeon F. H. Bowman, from *Ohio* to *Delaware*.

October 19, Surgeon F. E. McCullough, from San Francisco Training Station, to *Florida*.

Surgeon T. W. Richards, from *Florida* to *Maine*.

P. A. Surgeon G. W. O. Bunker, to Navy Yard, Portsmouth, N. H.

P. A. Surgeon G. E. Thomas, from Navy Yard, Portsmouth, N. H., to *Utah*.

P. A. Surgeon, L. W. McGuire, from *Maine* to *Rhode Island*.

October 20, Surgeon P. S. Rossiter, from *Colorado* to Training Station, San Francisco, Cal.

P. A. Surgeon R. I. Longebangh, to Navy Yard, Mare Island, Cal.

NOTICES.

CENSORS' MEETING OF NORFOLK SOUTH DISTRICT.—Meeting of the Censors of the Norfolk South District will be held at the office of the Secretary, 37 Holbrook avenue, South Braintree, Thursday, November 11, at 2 p.m.

Candidates for admission should bring their diplomas.

F. H. MERRIAM, M.D., *Secretary*.

The Fourth "Authors' Evening" of Ten Papers, "A Second Contribution to the Neurology of Childhood," by Walter B. Swift, M.D., and assistants: C. A. Osborne, M.D., Ph.D., second assistant; Miss Jennie Hedrick, voluntary assistant. At the Voice Clinic, Psychopathic Hospital, 74 Fenwood Road, November 19, 1915, at 8 p.m. 1. The Signs and Symptoms of Stuttering. 2. The Physical and Mental Examination of Stutterers. 3. The Thymus as the Seat of Stuttering—Browning. 4. Relation of Stammering to Right and Left-handedness. 5. Medical Aspects of Stuttering from the Teacher's Standpoint. 6. Incongruities in the Freudian Concept of Stuttering. 7. Five-Minute Summary of Spirometer Findings in Stutterers. 8. Further Psychological Steps in the Recovery of the Same Stutterer. 9. Psycho-physiological Analysis of Stuttering. 10. Locating the Speech Center by Hand Motions in Stutterers. First Note.

Physicians and medical students are invited.

Kindly drop a postal if you expect to attend to 110 Bay State Road, Boston, Mass.

SOCIETY NOTICES.

MASSACHUSETTS STATE NURSES' ASSOCIATION.—The autumn meeting of the Massachusetts State Nurses' Association will be held at Hotel Brunswick, Boston, Saturday, Nov. 13, 1915, at 3.00 p.m.

Address, Miss Anne W. Goodrich, R.N., asst. professor, dept. of nursing and health, Teachers College, New York City. Subject: "The Value of State Registration and Inspection of Training Schools."

Discussion.

THE MASSACHUSETTS LEAGUE OF NURSING EDUCATION will meet at the Central Directory, 636 Beacon St., Boston, at 11.00 a.m., the same day.

SARA E. PARSONS, *President*,

CHARLOTTE W. DANA, *Cor. Sec.*,
24 McLean St., Boston, Mass.

NEW ENGLAND SOCIETY OF DERMATOLOGY AND SYPHILIS.—The next meeting will be held at the Boston City Hospital on Thursday afternoon, Nov. 18, at 3.30 p.m. Those interested are cordially invited to attend.

CHARLES J. WHITE, M.D., *Secretary*.

APPOINTMENTS.

UNIVERSITY OF PENNSYLVANIA. *Dr. William G. Spiller* has been appointed professor of neurology to succeed *Dr. Charles K. Mills*, who has become professor emeritus.

UNIVERSITY OF CINCINNATI. *Dr. Edward F. Malone* has been appointed associate professor of anatomy and *Dr. John C. Donaldson* instructor in anatomy.

CORNELL UNIVERSITY. *Dr. Charles B. Morrill* has been appointed instructor and *Dr. Robert Chambers* assistant in anatomy.

ALBANY MEDICAL COLLEGE. *Dr. Wesley M. Baldwin* has been appointed professor of anatomy.

RECENT DEATHS.

DR. EDWARD P. COLBY, who died recently in Boston, was born at Cincinnati on March 4, 1839. After obtaining his preparatory education at Claremont Academy, New Hampshire, he received the degree of M.D. in 1861 from the Long Island Hospital Medical College. He served throughout the Civil War as assistant surgeon in the United States Navy. Subsequently he settled in the practice of medicine at Wakefield, Mass., but removed to Boston in 1890, where he became professor of nervous diseases at the Boston University Medical School. He was consulting neurologist of the Massachusetts Homeopathic Hospital, the Westborough Insane Hospital and the Clinton Memorial Hospital. He was a member of the American Institute of Homeopathy, the National Society of Electro-therapeutics, the Massachusetts Homeopathic Medical Society, the Massachusetts Surgical and Gynecological Society and the Boston Homeopathic Medical Society.

DR. FRANK HERBERT DANIELS, a graduate of Harvard College in the class of 1879 and of the Harvard Medical School in 1884, died at his home in New York City, October 30, 1915. He was born in Charlestown, Mass., September 1, 1856, joined the Massachusetts Medical Society soon after graduating from the Medical School, and moved to New York the following year. There he had practiced since, being at one time physician to Manhattan Hospital and curator of Randall's Island Hospital.

DR. EDWARD E. FROST, who died on October 31, at Worcester, Mass., was born at Vernon, Vt., in 1850. He removed to Worcester in 1869 and after studying for a time in a dental office there, he entered the Harvard Dental School from which he graduated in 1875. After practicing his profession for a time at Worcester, he retired in 1880. He is survived by two daughters and three sons.

DR. JOHN HENRY HUDDLESTON, who died of pneumonia on October 30, in New York City, was born in Boston on July 11, 1864. He received the degree of A.B. from Harvard in 1886, that of A.M. in 1887 and that of M.D. in 1891. Since 1892 he had practiced his profession in New York. He was a member of the American Climatological Society, the American Public Health Association, the National Association for the Study and Prevention of Tuberculosis and a trustee of the New York Academy of Medicine. He was Carpenter lecturer at the Academy in 1902; and in 1903 was secretary of the American Committee for the fourteenth International Medical Congress at Madrid.

DR. EDWARD OSGOOD RICHARDS, who died on October 29 at Salem, Mass., was born in that city on January 8, 1856. After graduating from the Boston Dental College, he settled in the practice of his profession at Salem. He is survived by his widow, one daughter and one son.

DR. WILLIAM H. SCOTT, who died recently at Brookline, Mass., was born in 1832. He received the degree of M.D. from the Berkshire Medical College, and at the time of his retirement had practiced his profession for fifty years.

DR. WILLARD KNOWLTON DYER, who died on Oct. 18, in Boston, was born at that city in 1851. He obtained his medical education at the Harvard Medical School and had made a special study of diet in renal and diabetic disease. He is survived by one daughter.

DR. HERBERT E. KNOWLTON, who died on Oct. 24 in San Diego, Cal., was born at Belfast, Maine, in 1867. He received the degree of M.D. in 1891 from the Harvard Medical School and for twenty years subsequently practised his profession in Cambridge, Mass. Since his retirement in 1911 he had lived in California. He was a non-resident member of the Massachusetts Medical Society. He is survived by his widow.

THE MIDWIFE PROBLEM.*

BY A. K. PAINE, M.D., F.A.C.S., BOSTON.

To a certain extent the title of this paper is a misnomer inasmuch as the midwife represents but a part of the general obstetric situation with which we have to deal. An attempt to confine oneself to a single aspect of this great problem is not to deal broadly with the subject presented, but the midwife, representing as she does one of the weaker links in the chain which supports this important part of our social fabric, becomes the object of our most marked attention.

In this community the general trend of thought is to ignore the possibility of benefit to be secured from the continuation of that ancient institution, the midwife. This attitude is generally carried to the point that the average man in his medical upbringing is imbued with the idea that the midwife merits none and has no defence. At least this was my personal experience and it was only gradually borne to me by the wealth of literature on the subject continually appearing in our journals, that our method of easy disposal of the midwife problem, was not apparent to the country at large. It was evident from the number and conflicting na-

ture of the articles in question that the last word on the subject had not been said, and it was also apparent, did one stop to consider, that the midwife played a considerable part in the practice of obstetrics in Europe.

With this in mind, and a considerable interest in the obstetric situation as it exists, an attempt to secure more information on the subject was begun with the object of formulating an opinion which would be in keeping with the facts. Proceeding with this as the object, a rather extensive communication was carried on with various people interested in the subject throughout the United States. This included the leaders in the practice of obstetrics, officials whose work brought them in contact with obstetric problems, boards of registration in medicine, boards of health and various local organizations.

Briefly, the communications were requests for information and opinions regarding the obstetric situation generally and the midwife in particular with such facts as would aid in a study of the matter. I would take this opportunity to express my great appreciation of the kindness and courtesy with which my requests were received on every hand, and my great obligation for the many and extended communications from the various people mentioned. The replies could be easily catalogued as statistics of the opinions and facts regarding the whole subject of midwifery in its present status, but it would perhaps be more interesting to outline briefly the impressions to be gathered from this wealth of material.

* Read before the Chirurgical Society of Boston, April 23, 1915.

The striking feature of it all was what might be described as the uncertainty of the medical profession generally regarding the whole subject. It was usually apparent that the minds of many were in doubt as to the best and final solution of the obstetric problems which are so evident. Further the replies embodied two general possibilities. The first might be described as the ideal solution of the care of the parturient woman. This ideal is, that every such woman is entitled to all the benefits to be derived from care by a trained obstetrician, that such ably trained obstetricians should be in every community in sufficient numbers to care for all maternity cases and that by the high character of their work they would automatically suspend the activities of poorly trained physicians, midwives and every other agency which did not maintain this high degree of obstetric skill. The first premise—that every pregnant woman is entitled to the best that science can secure—needs no comment. The remainder of the idealistic program immediately raises a myriad questions, all of which resolve themselves into one of practicability, and therefrom has developed the second group of ideas which might be described as the practical method of dealing with the subject, and I am constrained to say, that the practical methods almost invariably include the trained midwife as a part of their procedure.

With but one or two exceptions, the opinions all agree that the midwife, as she exists at present in the United States, represents an institution intolerably below the standards which should be legitimately demanded. Perplexity as to the solution was the keynote of all these communications. The tendency, however, was toward the training and supervision of the midwife, and various steps, as you know, have been taken here and there with an idea of bringing about this regulation. In some places the midwife is legally ignored. In others, she is licensed to carry on her work, but without particular supervision. In still other states, some attempts at supervision are made, with some inquiry into the qualifications of the practitioners of this art. In others attempts have been made to secure these qualifications as well as to regulate the practice. New York, Pennsylvania, Maryland and Illinois may be cited as examples of states taking the most advanced stand in the matter of securing properly trained midwives.

Another opinion almost universally expressed concerned the unsatisfactory state of obstetric teaching and training in the medical schools. Dr. Moran of Washington expresses the general idea on the subject when he says, "In my judgment the medical curriculum needs to be materially changed. Surgery is today made the intensive course to the disadvantage of general medicine and obstetrics which are certainly of more vital importance to the recent graduate. The interne as a rule, is so enamored of the knife that he gives scant attention to the test

tube, stethoscope and microscope. Obstetrics should be made the intensive course of the curriculum and I am constrained to believe that major surgery should be restricted to post graduate work. Much of the time now spent in the amphitheatre could be more profitably devoted to study and experience in the general practice and obstetrical wards."

In closing this very brief résumé of the opinions gathered from these communications, it is fitting to add that Boston represents the stronghold of what might be described as the anti-midwife attitude. It should also be added that throughout the country the condemnation expressed was not only of the midwife as she at present generally exists, but also of obstetrics as it is practiced by many physicians. Dr. Williams of Baltimore sums the situation up quite definitely when he says, "In regard to the midwife problem, we are in a very difficult position, as in my experience the average doctor who treats the poor, and sometimes the rich as well, does quite as much harm as the ignorant midwife. Consequently, I do not think that we are justified in trying to abolish her until we can put our own house in order. I therefore feel, that the first thing for doctors to do who are interested in the subject is to see that steps are taken to bring about proper obstetrical teaching in our medical schools and the foundation of institutions where that subject will be taught as a science rather than as a mere art. As long as students are taught that obstetrics consists merely in the delivery of women so long will it remain a discredited branch of medicine. After we have brought about these changes and are prepared to offer properly supervised outpatient care to the poor, then we should take up the question of abolishing the midwife."

On the other hand, a large number of the leaders of the medical profession headed by Dr. Jacobi and Dr. Edgar of New York, take another view and feel that the proper and practical solution of the whole problem is to be secured through the medium of the properly trained and supervised midwife in conjunction with the general better training of those physicians who practice obstetrics.

From the wealth of facts and opinions secured in the pursuit of this study, various deductions may be drawn. Obstetrics as a branch of medicine has been highly developed and is on a par with the rest of that science, but as such is practiced by the very few. As practiced by the rank and file of physicians it occupies a considerably lower plane than does the general practice of medicine and surgery, and as pursued by the few, represents a very low type of medical service. Why is this so? The practice of medicine as a whole is carried on by individuals as a private undertaking, unfortunately, but nevertheless truly, representing not only a devotion to an ideal but a means of livelihood. This fact applied

to obstetrics discloses a very unpleasant truth. The time necessary to care properly for an obstetric case, according to present-day standards, cannot be given for the small financial return that the great majority of people can afford or expect to pay for such service, and the result is that this class of work is done because of its entering into general practice in spite of the inadequate return, or, worse, is poorly done by an inadequately equipped attendant for the inadequate fee, this latter including the midwife as she at present generally exists in this country.

This state of affairs has borne itself upon the public mind to a certain extent with the results that various private and institutional attempts to deal with the problem are evident. Nor must we neglect the part played by the institutions for medical training which in serving their own ends have also supplied a portion of various communities with excellent obstetric treatment.

It would, perhaps, be natural to inquire why this chaotic state exists as regards the practice of obstetrics, when, comparatively speaking, surgery as a whole, of which obstetrics is a branch, is standardized in a measure at least. The unpleasant statement was made that poor obstetrics seems to bear some relation to an inadequate financial return. Why is the return inadequate? Everyone has observed the rather anomalous situation of a family paying a very considerable sum easily and without apparent reluctance for some surgical operation, when the same family expects to pay for attendance during pregnancy and confinement the most meagre fee.

To understand this peculiar state of affairs we may perhaps with advantage consider what might be stated as the psychology of medicine. The science of medicine occupies in the eyes of the public at large an anomalous position. It is not regarded as an immutable science, but as a mixture of science, pseudo-science, and in part as a belief. We may even see the belief predominate to the exclusion of all else, and like that great example of belief, religion, it is found in many guises and forms. The average person by nature is more or less a practitioner of healing, with many ideas and convictions deeply rooted. In one of these deeply rooted convictions we are particularly interested as we discuss the subject of obstetrics. This is the idea which is held by the community at large, that the giving birth to a child is a manifestation of nature pure and simple. And nature in this, at least, is considered practically, if not entirely, self-sufficient. Nature requiring but a minimum of assistance to complete her work in her obstetric undertakings, obviously such a minimum of assistance should merit but a minimum of regard with the little that that entails. This minimum assistance has been rendered from time immemorial and in it we can see the obvious development of the midwife.

It is hardly necessary to indulge in a description of the transition from the earlier attempts at assisting nature, to the trained midwife as she at present exists in Germany, for instance. The midwife as an untrained practitioner of this art merits the condemnation that she has rightly received on all sides, but the midwife as an institution developed in some parts of Europe represents an attempt to solve a great problem, the culmination of much thought and study, and the whole representing conclusions we cannot lightly disregard. It is generally conceded that in Germany the most advanced steps have been made in the perfection of the community life. The nature of the government is such that should a certain procedure in the light of careful investigation seem desirable, that procedure can be put in force without such difficulties attending establishment of new civic regulations and procedures as would be witnessed in this country, for instance. Should it be decided after extensive investigation in Germany, that the midwife could with advantage be supplanted by any other agency, that supplanting could, and apparently would, be done.

The lesson we may learn from the method of dealing with the problem is not that the midwife institution represents perfection, but rather that it is the most practical means available. Attempting to apply the experience of other countries to this, we are confronted first with the necessity of public education which must precede all progressive legislation or regulation and which might obviously become a difficult matter. In the light of our experience in securing beneficent legislation concerning the public health, witness, for instance, the difficulties surrounding an attempt to secure such a desirable enactment as would ensure clean milk. In other words, it is questionable whether our community life would lend itself to the proper regulation of a work of this kind, in part because here an idea of central authority has not been developed to the point where community efficiency supplants individual efficiency.

There was one theme which pervaded all the writings and communications I was privileged to see, a theme often submerged, but always recurring and that theme was, that the midwife was "practicing medicine without being a physician." It has occurred to me that much of the adverse attitude of the medical profession to the properly trained midwife has unconsciously developed from this idea, and the question arises, if this work were carried on by trained nurses under the supervision of competent obstetricians, would not a different attitude toward the whole matter develop? This is not offered as a suggestion but rather as a possible explanation of some of the distrust with which the whole subject is viewed, and this without attempting to mitigate the part played in the production of

this distrust by the appearance on all sides of women practicing the art of midwifery with but the slightest, if any, qualifications to carry on that work. Nor should we ignore the fact that not even in Germany, where the development of the system and its regulations are carried out with regard to the minutest detail, which characterizes the German mind, is the system entirely above reproach in the eyes of those most interested and qualified to judge. Its continuance is partly the result of long established custom and partly because no better method has apparently been devised which is practical of application.

Emmons and Huntington, in an article discussing the subject, described workings of the German system and, as the result of their own observations, condemn it strongly. In the course of the article they quote from the *Journal of the A. M. A.*, which states that "the midwife is not so well regulated in this country as in Europe, but the harm done is probably less, since the midwives are not so numerous," which might seem to offer in several respects an opportunity for considerable argument, a statement which is based apparently on an opinion rather than on available demonstrated facts.

Leaving the general aspects of the question temporarily, let us briefly review the situation as it exists in our own community where we personally are most concerned. Boston's position as a leader in the advancement of the science of medicine is sufficiently well recognized to need no description. The work for the betterment of the general practice of medicine includes as well that branch devoted to the practice of obstetrics. The individual application of the knowledge and skill as exhibited by the leaders in this subject is of the highest order and merit. The teaching of obstetrics here is as complete as anywhere in the country, though that is saying but little, and yet the practical application of this comparative excellence to the whole community is conspicuously lacking. That every woman confined in Boston does not receive all the benefits available from high-grade obstetric care is due not to the absence of high obstetric ideals, but rather to the incomplete organization or machinery to supply that high-grade service to everyone.

The presence of medical schools increases materially the total number of obstetric cases that are properly cared for, which is a distinct advance Boston has over communities not supporting such schools, but even in Boston, the work done is not sufficient in volume to care for all the cases deserving of such care. It is to be noted also that the private charitable organizations doing the bulk of obstetric work among the needy, carry on that work as a part of the teaching propaganda of medicine. Without the medical schools, the number of cases receiving proper care during pregnancy would be re-

duced very materially, as must be obvious to anyone who would stop to consider.

In 1913 approximately 20,000 births occurred in Boston proper, not including the miscarriages which necessitate a material addition to the amount of work necessary to care properly for this class of patients. Statistics compiled by Emmons indicate that some 4,500 cases were attended in or by the various institutions doing obstetric work. A striking feature of this being that practically all of this institutional work was carried on by private organizations, while at least three-fourths of the cases were conducted as a part of the teaching of medicine. And, further, that of all the cases attended, less than 100 were cared for in municipal institutions. The city has practically left the whole care of its maternity cases to private organizations and physicians. Of the other 15,500 cases delivered in Boston, how many were cared for by private physicians for a return so small as to make it impossible to devote the attention necessary to the proper conduct of these cases? How many were delivered by physicians not competent to furnish high-grade obstetric service? How many cases were delivered by midwives, and what of the character of the midwives doing this work?

From time to time we receive from the schools of the continent well trained midwives. A part of their training includes the imbuing of a wholesome respect for the law. Finding that the law prohibits their practicing in Massachusetts, a considerable portion of these better class midwives refrain from attempting to practice. Those who do, represent a type without respect for legal or medical promulgations. The attempts in Boston to convict midwives of the illegal practice of medicine are interesting as a commentary on the peculiar status of the law bearing on the subject. In the last few years two convictions have resulted, but in both of these cases, while the practice of midwifery was the cause of attention of the authorities, the convictions were for a violation of the statutes in other respects than in practicing obstetrics without a license.

The attitude of the medical community toward the whole subject is not one characterized by a definite and comprehensive plan to deal with the problem, but seemingly favors continuance as at present until the idealistic state already mentioned is secured, until every one of the 20,000 or more cases per year receives the high grade obstetric attention correctly assumed to be their righteous due. Just how this is to be brought about, however, is not entirely discernable. The general scope of the plan seems to include more trained obstetricians, more dispensaries devoted to this work, and the elaboration of some such scheme as has been tried in Manchester, N.H., where various physicians have devoted a considerable time to the care of obstetric cases as a part of the work of a charitable organization.

The requirements of the situation demand a broad and comprehensive organization which can carry on a large amount of work, supplying good service on a large scale. The possibilities as have been indicated are: first, the trained midwife organization, the method adopted generally abroad as the not entirely satisfactory but most practical solution of the problem; second, the training in large numbers of obstetricians to carry on the work as individuals. Without discussing this factor at any length, it is interesting to consider a few possibilities. What does "the properly trained obstetrician" mean? It means the same as a properly trained surgeon about which we are hearing so much. It means seven or eight years in preparation with all that that implies. And is this extensive preparation for competition with the midwife in her special field?

The plea for better obstetric teaching in the medical school represents another method of attacking the problem of poor obstetrics and that it should result in a marked uplift is obvious. Unless the improved training is carried practically to the point that a skilled obstetrician results, may we not see an increase in what has been described as "meddlesome midwifery?"

The first and striking thing which impresses us is the lack of consideration given the subject by the community as a whole. What has been done for the sick poor generally? The many public institutions for their care, aided by numerous charitable organizations, attest that this branch of social service, at least, is rescued from obvious neglect. It is a commentary on conditions that exist that practically no provision is made by the city to care for its maternity cases. Should a human derelict, in vain search for amelioration of his misery, accept the frequent and easy opportunity to indulge in alcoholic relief and thereby meet with an accident he would be the recipient of services by an organization, which would furnish not only the physical means but the skill to treat his injuries in a manner which would compare more than favorably with those of an individual having unlimited wealth at his command. The care and treatment of such a case entails a very considerable expense, which is willingly met by the city. In contrast to this consider the plight of a poor woman about to give birth to a child, whose care and attention depends on the possible charity of some private individual or organization, or worse, the ministrations of a midwife, working without the pale of the law.

The problem is primarily an economic one, and as such, if not for humanitarian reasons, demands that the parturient receives throughout the course of pregnancy and confinement, the very best care that the community can provide. It must be apparent to anyone who considers the matter, that the present method, or lack of it, is inadequate to deal comprehensively with the situation, and that a radical and far-

seeing policy for the ultimate development of a method of properly conducting this part of our community existence is imperative. In the author's opinion there are but two possibilities for such a comprehensive plan. First, the establishment of a midwife organization similar to that in operation in other countries; or second, the adoption of this problem by the city as one in which its vital interests demand its official participation. In other words, that the city should adopt the care of its maternity cases in the same way that it adopts the care of the needy when they are ill or infirm for any reason. Why should not a city the size of Boston have an organization devoted to the care of obstetric cases, which are unable to secure for themselves proper obstetric treatment? Communities too small to support such an organization should pay for the proper care of obstetric cases, as is already done in many places. The striking difference between the conduct of such a municipal lying-in hospital and the other municipal organizations should be the realization that the treatment of these cases is not primarily the treatment of paupers, but rather an appreciation of the fact that the state demands that every obstetric case receives through its whole course, the care that the importance of such a case demands. The taking of such a step by this and other communities would of itself tend to solve the so-called midwife problem, which is but part of the problem of poor obstetrics, and bring about that which all seek, the fact that every parturient woman receives the attention commensurate with present-day obstetric standards. This solution of a vital problem is advanced as a practical method of dealing with a situation which cannot be allowed to continue without the development of some method to secure its amelioration.

CONCLUSIONS.

From this study of the various facts and opinions presented, the following conclusions might be reasonably drawn:—

1. Education in obstetrics in the various medical institutions in this country is considerably below the standards achieved in other branches of medicine.

2. The practice of obstetrics generally is very materially below the standards of general medicine and surgery, due first, to the educational deficiency in this subject; second, to a low type of midwife service, the result of a practical absence of regulation; and third, due to the fact that the general attitude of the public at large toward the practice of obstetrics is not in keeping with the dignity of that subject.

3. That no comprehensive and far-seeing plan is generally being developed to cope with the situation as it presents itself.

4. That there is a distinct tendency in many quarters to adopt the midwife as an institution,

after the manner of its conduct in the countries of Europe.

5. That, while the whole subject of the proper obstetric care of patients needing this service is one of great economic importance to the state, there is practically no attempt at meeting this situation by the state.

6. That it would seem that our method of government is not adapted to the rigid requirements which the properly regulated midwife demands.

7. That the state should assume the management and control of this work, which is of the greatest economic importance, as readily and as well as it assumes the burden of caring for such of its citizens as are incapacitated by ill health or age.

THE PREGNANCY CLINIC AND THE MIDWIFE: A COMPARISON.

BY JAMES LINCOLN HUNTINGTON, M.D., BOSTON,

Assistant Physician to Out-Patients, Boston Lying-in Hospital; Third Assistant Visiting Surgeon for Diseases of Women, Boston City Hospital.

FROM some where, every once in so often, comes the plea for recognition of the midwife. Let us see why this is made in Massachusetts. In the first place we have a number of midwives, probably less than two hundred in the entire State, in active practice, but unrecognized, unregulated, and unprosecuted—for they are all defying the statutes of our Commonwealth. These women and the class of legal practitioners of medicine with whom they are closely associated are in the main responsible for this indefinite agitation.

Another group of agitators are those physicians who see all about them the results of bad obstetrics. They either feel that the midwife, as she exists today, is responsible for a large part of this state of affairs, and therefore she should be educated since she has not been suppressed; or else they feel that as the poor practitioner is responsible for most of this bad work it would be advisable to adopt the European trained midwife, feeling that any change must be for the better. Others urge this change because they feel that the immigrant will always cling to the midwife; they fail to understand the requirements of modern obstetrics, and believe that it is possible to educate these midwives so that they can give proper care to these immigrant women.

Now this present situation in Massachusetts is very far from being ideal. But the solution by changing the laws and recognizing the midwife is certain to make for a worse obstetrical situation rather than a better.

In the first place the responsibility for the brand of obstetrics practised so generally in Massachusetts today rests on the shoulders of the untrained and improperly trained practitioners. These outnumber the midwives ten to one, and they know little, if any, more about obstetrics than do the midwives with whom they are in competition. The medical schools which prepare these practitioners are also responsible for the conditions as they exist today; for they

allowed these physicians to enter practice without adequate training but with the idea that operative obstetrics is child's play, whereas operative surgery requires post-graduate training.

The standards required for admission to practice medicine in Massachusetts have been so low that many men of inadequate training have come to our State as a haven of refuge. Obstetrics is admittedly the poorest taught subject in the medical schools of America today. The result is that these physicians know practically nothing about obstetrics. Yet they have been educated out of the healthy dread of meddling which the untrained midwife possesses.

We see the background of obstetrical practice in the State. Let us for a moment see how this proposed change would work out. What is to become of the midwives in practice today? Are they to be allowed to practice without any more education than they now possess?

Of course when education of the midwife is suggested, one means training in a lying-in hospital or out-patient dispensary, so arranged that the midwife shall be fitted to take the responsibility of the case. Merely giving an ignorant woman an opportunity to observe for a few months the conduct of normal labor, and assist in the after-care, is not education but only the familiarity that breeds contempt.

At the present time there are not enough obstetrical opportunities in the hospitals of Boston, our only medical school center, for the proper education of all our medical students in residence. Thus we see that the midwives would have to be educated outside of Boston or else their education would be at the expense of the future medical practitioners. But outside of Boston there are few, if any, lying-in hospitals properly equipped and doing a sufficient amount of work to undertake this new departure. It means, therefore, the establishment of new schools. How are you going to raise money to build and equip these schools? How are you going to get pupils to fill them? Supposing you could force the graduates of the famous European schools for midwives to enter these schools, would they profit by the training? A large proportion of the women practicing as midwives in Massachusetts have this training—over 36% in 1912,—also these trained women have the largest practice as a rule. Thus we see that we should have many problems to solve before we can educate the midwife in Massachusetts.

It would not be a difficult problem to establish the machinery for licensing the midwife. She would have to appear in person at the State House and pass an examination and pay a registration fee, that would be all; but how would it be possible to prevent the unlicensed midwives from practicing? We see how futile the law is at present; all the women practicing as midwives are breaking the law now, yet very few are prosecuted annually. Would more be prosecuted if some midwives were licensed and only a

few were violating the law? When we have seen the numerous violations of the law governing the practice of medicine in Massachusetts and the indifference with which these violations were met, it is hard to believe that the license to practice as a midwife would be worth very much. Law that is not backed by public sentiment is futile; public sentiment in Massachusetts is absolutely indifferent as to whether midwives practice or not or whether they are or are not licensed.

But supposing the machinery for the proper education of the midwife is established and public sentiment is aroused to enforce the midwife laws, is it going to be an easy thing to regulate the midwife in her practice? Proper regulation means supervision by trained physicians and nurses. This would be expensive and could not exist without the loyal support of the police department.

After a few arrests and convictions the system would probably work as well as the midwife system does in England or in Germany, certainly no better, provided the medical education of the midwives and of the physicians on whom they would be compelled to call for help, were up to the European standard. In other words, the midwife system depends finally on the efficiency of the medical profession, for the midwife must keep in constant touch with a physician in all her abnormal cases.

Now by developing a midwife system a dual standard is established in obstetrics. Unlike all other branches of medicine, there would be two classes of practitioners,—one to care for the normal uncomplicated case among the poor, the other to care for normal cases except among the poor, and for abnormal cases wherever they occur. This seems hardly a fair division of service at best. Is there no other alternative?

We are told right along that the immigrant cannot be weaned from the midwife, and that is the strongest argument given by those in favor of the midwife and her education and regulation. That she not only can be, but has been, weaned from the midwife can be seen by the casual observer who will spend a morning in the Pregnancy Clinic of the Boston Lying-in Hospital. Every day Russians and Italians are flocking to us for care. No one possessed of any knowledge of the essentials for the proper care of pregnancy, labor and the puerperium would pretend that midwives, no matter how well trained they are, could give the care these patients are receiving.

The Boston Lying-in Hospital was the first to establish a real Pregnancy Clinic in Boston in connection with its other work, and has today by far the largest Pregnancy Clinic in New England. It was started in 1911 and now there are at least three other similar clinics in Boston, besides others in smaller cities, all working along the same lines.

Let us now glance at the care given as routine and the results obtained last year.

All patients are urged to come as early in their pregnancy as it is possible, and every year more patients are coming to us before the fifth month, many for the diagnosis of pregnancy. A careful history is taken, and the details of the proper hygiene of pregnancy are explained. Every patient has a complete physical examination at the first visit, including a Wassermann test (this test is carried out at the State Board of Health Laboratory), an examination of the urine, and a determination of the blood pressure. Every patient is required to return for examination at the end of four weeks or sooner if any symptoms arise. Should any abnormality be noted the patient is told to return promptly, the exact day being specified, to see how treatment is affecting the condition or to establish more definitely the line of subsequent treatment of the case. Should any grave complications be noted, the patient is referred to the Hospital for treatment in the wards. All cases where the pelvis is so contracted as to offer any question as to the outcome of the labor, are referred to the Hospital for examination by the visiting physician.

All patients making their subsequent visits are carefully questioned as to how they are following out the rules for the hygiene of pregnancy, their blood pressure is taken and their urine is examined. Many of our patients who are to be delivered in the Hospital are visited in their own homes by our Pregnancy Clinic nurse, who goes over carefully all the points touched upon in the Clinic and does what she can for the comfort and welfare of the patient. Patients who are to be confined in their own homes are similarly visited by the nurses from the District Nursing Association. These visits are made about every ten days or oftener if necessary.

Of course, most of our House patients make some return to the Hospital for the treatment they receive. Our out-patients do not, being merely allowed to make a voluntary contribution to the support of the Hospital. These voluntary contributions, averaging about 76 cents per patient, brought in over \$1500 last year.

The results obtained in the Pregnancy Clinic of the Boston Lying-in Hospital last year are as follows:

NEW APPLICANTS FOR TREATMENT.

Referred from the hospital.....	526
Referred from the out-patient department.....	1250
Referred for consultation from other institutions	14
Subsequent visits.....	2727
First visits of babies.....	20
Subsequent visits.....	16
Total number of visits.....	4502
Total number of new patients.....	1790
Remaining under observation from previous year	268
	2067

Subsequently delivered in the hospital.....	432
Subsequently delivered in the out-patient department	1055
Not pregnant.....	16
Removed from district.....	11
Discharged to private physicians.....	12
Ceased attendance or otherwise provided for.....	219
Consultations from other institutions.....	14
Died undelivered.....	2
Remaining under observation.....	306

Of the 2067 women under the care of the Pregnancy Clinic during the year 1914, 592 presented the following complications of pregnancy:

Contracted pelves of varying degrees.....	228
Albuminuria without other signs of toxemia....	137
Definite symptoms of toxemia.....	72
Elevated blood pressure without other signs of toxemia	47
Heart lesions.....	41
Ante-partum bleeding.....	17
Miscarriage	5
Acute hydramnios.....	6
Pylitis	6
Phthisis	4
Syphilis	4
Gonorrhea	3
Hemorrhoids (giving acute symptoms).....	3
Diabetes	2
Flat foot (acute).....	2
Congenital malformation of the rectum.....	1
Cyst of mammary gland.....	1
Epilepsy	1
Exophthalmic goitre	1
Fibroid uterus	1
Mastitis	1
Ovarian cyst	1
Peritonsillar abscess	1
Phlebitis	1
Placenta praevia	1
Pruritus vulvae	1
Purpura	1
Scarlet fever	1
	592

Of the 1487 women from the Pregnancy Clinic delivered in the Hospital or in the Out-patient Department there were

Discharged well	1418
Discharged to private physicians.....	8
Discharged to other institutions.....	3
Discharged dead	6
Remaining under care	52
	1487

The work of such an institution is educational. We educate the community to appreciate the value of good obstetric care; we teach our patients how to obtain this care and our students how to provide it.

We feel confident that this is the solution of the obstetrical problem in Massachusetts, offering far better results than could the midwife, no matter how well trained and regulated. By the increase in the number of such institutions we are encouraged to believe that the midwife will gradually disappear, being superseded by the modern obstetrical dispensary.

CLINICAL RECORDS IN RELATION TO TEACHING AND RESEARCH—A PLAN TO PROMOTE CONSERVATION AND UTILIZATION OF MATERIAL*

By EUGENE S. KILGORE, M.D., SAN FRANCISCO.

[From the Department of Medicine, University of California.]

In connection with the reorganization of the University of California Hospital in 1912, one of the important problems presenting itself was that of hospital records. To the teacher and research worker especially, very few details connected with the running of a university hospital equal in importance the clinical record system. From the economic standpoint alone, it is clear that for this type of hospital where the cost per bed per day is unusually high, a system which makes possible the greatest utilization of past material as well as present has a high value; and if considered solely as an investment, it would more than justify the small extra expense required. It is the duty of all hospitals, however, and especially university hospitals, to take a broader view of economy than the immediate saving of dollars and cents. The ultimate benefit of the race, the lessening of disease and its more efficient alleviation through medical research are justly coming to be regarded as the most profitable type of benevolent investment. And the charitable hospital that neglects opportunities to advance medical science is like the manufacturer who throws away valuable by-products. That the great majority of American hospitals are following such a short sighted policy of neglect is truer, I believe, than is generally appreciated. Not only is the proper kind of research on current cases too seldom undertaken; but, for want of sufficiently accurate, complete and accessible data, a vast amount of useful material is constantly thrown beyond the reach of those in the future who would utilize it.

It was such considerations which prompted and, we believe, more than justified our small increases in time and money expenditure for developing the hospital record system. The university was fortunate at the outset in adopting the general plan of records followed at the Massachusetts General Hospital, and later in securing for the custodianship of the records Miss Genevieve Clark, who received her training under Mrs. Grace W. Meyers. The details of this system have been ably presented before this association by Myers,¹ Hollings² and Howland³; and here it will be necessary only to reemphasize the following points: (1) The necessity for adequate administrative machinery to insure getting uniform and correct data in regard to patients'

names, addresses, etc.⁴ (2) Permanency of the records. Only good rag paper⁵ and non-fading ink should be allowed.⁶ By all means the records should be substantially bound and kept in a dry, fire-proof place. (3) Economy in paper, binding, and fire-proof storage as well as convenience in handling will result from using both sides of the paper and limiting the number of extra laboratory sheets, etc.

COMPLETENESS AND ACCURACY OF CLINICAL RECORDS.

The hope of having anything but haphazard and fragmentary clinical records should be abandoned by any institution whose visiting staff will not give time and energy to the undertaking. An essential element is standardization of the general form of records and method of filing; and to this end by far the most business-like and effective plan is to give over the direction of the record system to some one member of the staff who has the requisite insight and abundant interest in the undertaking and patience to carry it out. He will encounter a large number of details, and for a long time will have to educate other members of the staff as well as internes and nurses. Such an educative campaign is helped by frequent reports sent to the staff indicating for each service such items as: Number of operations or autopsies performed before the clinical diagnoses were recorded, number of records turned in with no blood pressure reports, etc., etc.

An unusual advantage is enjoyed by university hospitals in being able to train interns for two or three years before they begin their service. In the University of California a few weeks after the second-year medical students begin the course in physical diagnosis and history taking, they are given an outline of history and physical examination records, which they follow from then on in reporting their cases, and which is prescribed for the use of interns. The exact form of this outline is not so important as it is to have uniformity in the general arrangement, which lessens the number of important facts overlooked in the writing and greatly facilitates later endeavors to hunt up statements that are wanted. Much stress is laid upon history taking, and students are given a good deal of practice in it; the aim in teaching being first for accuracy and completeness and second for conciseness and the elimination of irrelevant matter. Hospital interns are chosen from among students who are known to write acceptable clinical records. We are opposed to the idea of allowing student histories to go into the hospital records, on the ground that the high value of these records merits for them the best help available.

One common defect of clinical records is that they do not make clear to the one who reads them several years later the exact nature of various procedures mentioned, e.g. the deter-

* Presented before the American Hospital Association, June, 1915.

NOTE.—This article together with Dr. J. L. Whitney's article on page 772 of this issue is part of a series of articles on the subject of clinical records. Others in the series are appearing in the *California State Journal of Medicine*.

mination of sugar or urea in the blood, or the technic of blood pressure measurements. Incomprehensible abbreviations are also prone to creep into the records. The latter may be avoided by supplying a list of permissible abbreviations¹ and insisting on their exclusive use. This may well be incorporated into the history outline prescribed for students and interns and a copy bound with the records. The usefulness of the abbreviations will depend upon their simplicity and fairly obvious meaning.

The record forms² should be carefully planned to encourage completeness in reports. Thus, in connection with the differential count of leucocytes should be stated the number of cells on which it is based, since this will very largely determine its value. For the same reason the test used for occult blood, the method of determining sugar percentage, of reading blood pressures, etc., should all be indicated.

Ambiguity in other reports we have planned to avoid by the use of a "ward reference book"³ containing the exact description of various clinical procedures in use which have not as yet become well established in the text books. The book has loose leaves and an alphabetic index; and whenever it is decided to try out something which is not already a ward routine, for example, functional liver tests, someone looks up the literature and writes out the exact technic to be followed, together with references and the date when the addition to the book is made. A copy of this ward book is bound with the first volume of the medical records as a sort of preface; and from time to time additions or changes are to be noted in later volumes, so that at any future time it will be possible by comparing the data of a given history with the dates on these introductory pages to know the exact technic in vogue at the time. Aside from this help in clarifying the records, this ward reference book is found very useful to interns and students who are set at tasks that are new to them. The book also contains the prescribed history outline and examples of the exact form in which various routine clinical reports are to be entered.

The training school for nurses as well as the medical school is a valuable asset in the development of good clinical records. Nurses are readily taught the technic of blood pressure determinations, using the palpatory index for systolic pressure and the change or disappearance of sounds for the diastolic. With proper supervision, we believe their readings to be reliable. The result of this training is that nurses in the out-patient maternity service can keep track of patients' blood pressures; also that in ward cases, when desirable, blood pressure readings may be taken as often as the temperature and pulse. This is not at all inconvenient when a machine is left clamped to the bed and perhaps even the cuff left *in situ*. Nurses readily do this as part of the ward routine, whereas the inconvenience of it on the part of the staff is practically prohibitive. Nurses are also trained to

count the heart rate by using the stethoscope and to record this as well as the ordinary pulse count when there is a discrepancy. If desired, they can also record specific gravity of the urine, its daily amount, and patients' weights.

Pupils in the training school are made to feel that accuracy and neatness in their reports are essential parts of their training; and since this attitude has been taken they respond almost without exception with pride and interest in making their records as good as possible. The charts are no longer hung on the beds where they are almost certain to be soiled; but each, together with the intern's clinical record, is safely kept in an aluminum binder in its pigeon-hole on the nurses' desk. One nurse at a time is responsible for the charts in a ward. The result is that although a great deal more matter is now put on these charts (7 to 9 separate graphs)⁴ and they cover more days than formerly (three weeks of four-hourly observations on a page), the need for recopying is much less frequent.

For the further promotion of completeness and accuracy, the records before filing are reviewed by the interns and residents, by the chiefs of service when they write the diagnoses, by the custodian of records, and finally by a member of the medical staff who is conversant with the diagnosis nomenclature and filing system, who makes sure that the form of the diagnoses will result in their proper filing, and who also adds secondary diagnoses which may have been overlooked.⁵

After filing, the records are still incomplete until every effort has been made to secure end results by an efficient follow-up system.^{6, 7} Such a system should embrace the records of all services and should include: (1) The psychological preparation of patients leaving the hospital. (2) The personal note so far as possible in the follow-up letters. (3) Provision for follow-up letters at shorter or longer intervals according to the nature of the case. (4) Cooperation on the part of the out-patient staff by transmitting to the house record room notes of important developments in cases seen by those who have been in the wards.

ACCESSIBILITY OF MATERIAL.

This is only secondary in importance to completeness and accuracy. Heretofore it has not to my knowledge been customary, even for hospitals with high standards, to do more in this direction than keep a diagnosis card catalog with perhaps cross references to the main complications and a separate set of cards referring to regions affected and to operations. While such a catalog is essential (it should contain many more secondary diagnoses than is usual)⁸ and admirably serves the purpose when it is desired to look up cases of a certain disease, it is of little or no help to the one who wishes to analyze, for example, cases with high white blood count,

cardiac arrhythmia, or albuminuria, or cases who have had vomiting or chest pain or dizziness as a symptom, or who have had typhoid fever in the past, or in whose families there was tuberculosis or obesity, etc., etc. Heretofore the only approach to such data has been through tedious hours or days or weeks of reading old records; and it is not surprising that comparatively few analyses from such points of view have been made. An experiment which we have carried out during the past two years has shown that with comparatively little initial expenditure of time, it is possible to make such facts as these as accessible as the diagnoses themselves.

A large card (reproduced herewith) the size of the record sheets (21.5 x 28 cm.) is printed on one side. At the top are spaces for the patient's name, age, hospital number, and diagnoses, etc.; and on the remainder of the card are headings to cover the main points in family history, past history, present illness, physical examination, laboratory and other clinical procedures. One of these "clinical index cards" is sent by the office with each case admitted to the medical service; and the intern while writing the regular history at the bedside underscores or negatives items on the card referring to history. *E.g.* he underlines "typhoid" if the patient has had typhoid fever, and he draws a circle through the word if there is no suggestion of typhoid in the history; but if, for any reason, the information cannot be obtained or is doubtful, the item is questioned or not marked at all. Since it is not desirable to fill the regular history with a great many negative statements which do not have an obvious bearing on the case, this card places on record many negative facts which otherwise would certainly not be preserved.

The remainder of the work on this index is done in the record room. After reviewing the marks made by the intern, the custodian proceeds to read the present illness, physical examination, the later clinical notes on the case, as well as the temperature and laboratory charts, and checks off the findings on the index card. For example, if the spleen is felt or is enlarged to percussion, the word is underlined on the card; if a heart murmur or cardiac percussion change is noted, "heart" is underlined; if astereognosis or cutaneous anesthesia is present, "sensory changes" on the card is underlined, and so on. It is obviously impossible and not desirable to go into further subdivisions on the index card. Its purpose is not at all to take the place of the clinical record, but to assist in finding the desired material in the records. If one wishes to collect the cases in which anesthesia or hypesthesia was found, a clerk in a few minutes will turn over the cards for a year and get together all the cases that have shown "sensory changes," and among these will be the desired material.

A few important treatments are listed, such as digitalis and intravenous medication. All the common laboratory and bedside clinical pro-

cedures have a place, such, for example, as gastric lavage, puncture of chest, spinal canal, etc., functional tests, complement fixation tests, sensitization tests, x-rays of various parts of the body, pulse and other tracings, photographs, physical measurements, etc. These are simply marked to show which were done. The results of tests are indicated only when they can be expressed by a mark or two (*e.g.* Wassermann, Widal, tuberculin, phenolsulphonephthalein elimination, etc.) Similarly the card when finished contains the highest and the lowest recorded figures for temperature, pulse, respiration, white blood count, hemoglobin, systolic and diastolic blood pressure, amount of urine, etc. The range of usefulness thus afforded is great. Within a few minutes one can have placed before him the records of all cases that have had fever with big spleen or low white count or positive Wassermann or blood culture; cases with headache as a symptom and systolic blood pressure above 170 or hemoglobin below 50%, etc., etc.

It will be observed that the card is designed to give unusually complete information regarding diagnoses, showing who made the clinical diagnoses and how far they were corroborated or amplified or contradicted by operation or autopsy. Pre-autopsy diagnoses have always been difficult to obtain in definite written form. A method for securing them with a good deal of certainty was devised by my colleague, Dr. J. L. Whitney. It consists of a form giving authorization for the autopsy and containing space for complete clinical diagnoses as well as a short résumé of the case for the benefit of the pathologist and space for the pathologist's diagnoses and remarks. Special comment is made by him on clinical findings which fail to receive clear explanation at the autopsy table. The superintendent will not sign this permit for the examination until the resident of the service has written his diagnoses. The sheet is bound with the records.⁴

An important space on the card is that marked "special." In it are written special items from the clinical notes which are not in the printed outline, often observations by members of the staff. For example, during thoracentesis, the patient faints and is given stimulants. The opportunity is quickly taken of observing what happens to blood pressure, pulse rate, etc. Following the regular description of the tapping in the record will appear an account of the incident under the underlined heading "syncope and circulatory stimulants." This caption will later be copied under "special" on the clinical index card for that case. Other examples are: "Blood pressure in arm and leg," "Respiration experiments," "Electrical conductivity of serum." To the worker who is doing a series of clinical experiments this offers a convenient and safe way of preserving his material; but its chief value lies in the saving of what would otherwise certainly be lost, namely the many valuable clinical observations made over a period of years in

NOTES:—Positive findings (e.g. an acknowledgment of a disease or a symptom by the patient or an abnormality discovered in exam. or lab. test) are underlined, negative ones marked out with a zero (0), and doubtful ones marked "??". No mark means information not obtained. A check (✓) means test done without indicating result. A heading underlined means an abnormal finding outside the list following it. A heading marked out with zero indicates a general negative statement in record, e.g. "reflexes normal."

routine ward work, especially those which are not frequently repeated.

It is needless to draw out the comparison of this *availability* and its ever expanding usefulness with the hopelessly lost condition of similar valuable observations which are numerous in the records of most good hospitals.

To the plan outlined above there appear to be three possible objections,—that it is complicated, that it is expensive, and that it necessitates trusting too much to the discretion of a person without medical training.

In answer to the first: It is as simple as it can be and yet give the results, and it works well. After two years' trial on the medical service, its use is now, with suitable modifications, to be extended in the University of California Hospital. It should not be undertaken, however, by any institution which is not prepared to employ a well trained custodian of records, and where there is not at least one member of the staff who will take a large personal interest and devote considerable time to it until it is well established. Profits are not to be reaped without this much invested.

In regard to the cost: The large clinical cards may cost one or two cents each; and the record custodian averages about 20 minutes or 13 cents' worth of time, in going over each medical history and transferring the data to the index card. This is estimated to be about one-third to 'one-half as expensive as it would be to have our records typewritten. Parenthetically, it may be added that, on grounds of accuracy and also of conciseness, we prefer originals to typewritten copies.

The member of the staff who checks up the work of the record clerk at first will have to verify each item on the index cards. Within a day or so an intelligent clerk will learn to transfer the material from the chart and laboratory reports with very little further supervision; and in a few days of training she will do almost as well with the history and physical examination. She should, however, have assistance permanently in this part of the work. After six months' experience, Miss Clark's practice is now to mark places where there is any question, and two or three times a month I spend half an hour with her reviewing the work. It looks as if in the future still less of my time will be required. The mistakes that one without medical training will make in this work are usually in checking off too much rather than too little; an unusual wording in the description of heart or lungs may lead her to record the findings as abnormal when they are not so. Since the cards are only to be used for finding data in the regular histories, the only result of such errors would be that when one is looking over a series of cases for some particular finding he will run across an occasional history that does not contain what he is looking for.

SUMMARY.

Experiences are reported in the coöperation of a university hospital, medical school and training school for nurses to promote accuracy and completeness of clinical records. To the same end a few suggestions are offered concerning methods of recording certain data, but these are being taken up in detail in other articles. In addition to the usual diagnosis index (which should be made to include many more of the secondary diagnoses) a plan is described for indexing many clinical facts which cannot be included among the diagnoses.

THE NOMENCLATURE AND CLASSIFICATION OF DISEASES IN USE IN THE UNIVERSITY OF CALIFORNIA HOSPITAL.*

By JAMES L. WHITNEY, M.D., SAN FRANCISCO,

Instructor in Medicine, University of California Medical School.

THREE years ago the University of California Hospital took certain definite steps toward enlarging its field of usefulness both as a servant of the public and as a teaching institution. This involved much work of construction and revision in bringing various details of hospital management into line with modern and efficient methods. Not the least important of these problems was that of finding or devising a system of nomenclature and a scheme of filing the hospital records which should accomplish certain desired objects.

The first of these objects was uniformity of nomenclature in diagnosis. The second was a method of indicating to the clinician, by means of a classification of diseases as complete as possible, the degree of fullness and accuracy desired in this particular, and, further, of indicating the desirability of establishing in each case various relationships, chiefly etiological, which were felt to be indispensable for the purposes of scientific research.

The third, and perhaps most important object was to have a system of filing which should render easily accessible the wealth of material too often permanently locked up in the hospital records. It seems hardly necessary here to dilate upon the fact that the investigations carried on in a hospital case, frequently of little enough importance to the patient himself, often acquire their chief value only when they can be

* Presented before the American Hospital Association, June, 1915.

NOTE.—This article together with Dr. E. S. Kilgore's article on page 767 of this issue is part of a series of articles on the subject of clinical records. Others in the series are appearing in the California State Journal of Medicine.

collated with similar investigations carried on in many other cases. Such collation is made almost impossible in the absence of a filing system which will enable the researcher to lay his hands easily upon the desired material.

Fourth, it seemed highly desirable that the method adopted should be flexible enough to allow of additions and modification in the light of new knowledge.

Fifth, the system must be as simple and practical as is consistent with the attainment of the ends desired. After considerable investigation it was decided to devise a system of our own, rather than to adopt any of those which were available to our hands. The reasons for that decision will be later discussed.

In the preparation of this scheme the requirements as given above were constantly kept in mind. A brief outline will be given here to illustrate how these requirements were met.

The attainment of uniformity in nomenclature was in most cases simple, though in others it involved the selection from a number of alternatives of that term which seemed most appropriate. As there is at present no final authority as to the standing of medical words, this selection had to be in many cases rather arbitrary. It has been generally the rule to adopt that term which seemed to be supported by the best usage, though, where possible, preference has always been given to simplicity, to English rather than to foreign words, and to good etymology,—and of this last it ought to be said that no other science has such a collection of bad etymology as medical terms display. Anyone dabbling in terminology must strongly feel the need of an authoritative body to revise thoroughly medical terminology, and bring medicine into line with all other sciences in this respect. In the preparation of this classification, however, temptation has been resisted, and nothing very radical has been done in the way of offering substitutes for terms where long use rather than respectable antecedents has given them standing.

One instance may, however, be given in which, for the sake of clearness, some departure has been made from common usage. This is in relation to the adjectives *acute*, *subacute*, and *chronic*. *Subacute* is not accepted in any case, occupying a position entirely too vague between the other two. In most instances it can be replaced by *acute*. *Acute* and *chronic* are very unfortunate words, since their meaning is never clear. Ordinarily they imply a short or long duration of the process, but no fixed limit can ever be set. Sometimes, as in the case of nephritis, *acute* means rather self-limited, while *chronic* implies incurability. In other instances *acute* is taken to mean a more violent form of the disease than *subacute* or *chronic*, quite apart from the time element. Again, the pathologist uses the terms wholly on the basis of the kind of cells present on microscopical examination. According to this usage a *chronic* (*i.e.*, a fibrous)

peritonitis can develop in a week, which to a clinician seems a good deal of an absurdity. In this sense *chronic* often signifies merely the scars that follow a once active process.

To meet this difficulty, it seemed best to discard at least the word "*acute*" in many instances where the situation was worst. For example, an infectious endocarditis is essentially the same process whether it lasts a week or two years, yet a two-year old process can hardly be called "*acute*." In this case we suggest the use of the terms "*active infectious*" and "*chronic fibrous endocarditis*." Inflammations of the serous surfaces offer a similar difficulty. In the case of pleurisy, for example, we recommend the terms "*fibrinous pleurisy*," "*fibrous pleurisy*" and "*pleurisy with effusion*."

The second point is that of completeness in detail, and accuracy. We wish to have the clinician state, and to be prepared to catalog, every pathological condition of any importance which a given patient may show. Such subsidiary conditions as secondary anemia, ascites, coma, etc., are ordinarily not set down as part of the diagnosis, but it often becomes highly desirable to collect, for comparison or for further study, all the cases which have shown just such conditions. We ask the clinician to supply these data, and we furnish as a model an outline of the lesions possible in a given disease. We further distinguish between complications (*i.e.* conditions dependent on the main lesions), and coincident conditions not causally related and in the cataloging this causal relationship is indicated.

We try to avoid collective terms as being insufficiently accurate, and ask that all lesions present in a complex be named. "*Genito-urinary tuberculosis*" is replaced by "*Tuberculosis of right kidney, ureter, bladder and epididymis*," while "*Cardio-renal complex*" gives way to "*Chronic nephritis and myocarditis*," or whatever the combination is believed to be. Of course a certain number of such less accurate diagnoses, as well as some symptomatic diagnoses, are unavoidable, often because the study of a case has not been finished, but provision is made for the listing of such cases under less specific headings.

Causal relationships, and etiology in general, have been considered of the greatest importance.

We wish to have stated in the diagnosis not only each lesion present, but its cause, and its connection with other lesions. The diagnosis of "*bronchitis*" is not complete unless we know the organism that caused it. The diagnosis of "*chronic endocarditis*," and "*syphilis*" is not satisfactory unless we are told whether the one was the cause of the other.

Where the etiology can be satisfactorily established, the diagnosis is primarily listed on the basis of the organism or other causal agent. No other of the systems which we have examined has gone to the same extent in grouping diag-

noses on the basis of primary cause. Such lesions as those of syphilis and tuberculosis have very commonly been grouped under an etiological heading. We extend this method to include every case where the organism or other etiological agent has been determined upon. In the infections the organism itself forms the basis of division rather than the pathological lesion: thus, the heading pneumococcus rather than pneumonia, and streptococcus viridans, etc., rather than rheumatic fever. The same correlation of cause and effect is sought after in other diseases than infections, as diabetic cataract, lead neuritis, amebic liver abscess. We try to connect even late results with their causes, as poliomyelitis deformity, fibrous endocarditis due to rheumatic fever, feeble-mindedness following encephalitis.

In order to accomplish this accuracy and detail in diagnosis, it has been found advisable that a member of the staff spend a short time once a week in running through the current histories ready for filing, and see not only that the diagnoses conform to the system, but that all the desired secondary diagnoses and etiological data are indicated in each case.

The next consideration was the arrangement of the catalog in such a way as to be of the greatest assistance to one who was gathering material for investigation. This necessitates the throwing together of those cases which are likely to be studied as a group. If tuberculosis was the subject of investigation, the tuberculosis section should include such lesions of every part of the body. If, on the other hand, diseases of the lungs were being considered, it was desirable that every lung condition be found in one place. Therefore, logic demands that tuberculosis of the lungs be filed both under the heading of tuberculosis and under that of diseases of the lungs. Every other filing system of which we know makes a more or less arbitrary assignment in such a case to one position or the other, but we see no particular objection to the idea of filing a single diagnosis in more than one place. It makes a little more work in card writing, but it also simplifies the cataloger's work. The rule is: "In case of doubt as to whether a diagnosis belongs in one place or another, file it in both."

The same system of double-listing holds for complications. We enter a case under kidney-diseases as "chronic nephritis with coma," and under the nervous system, as "coma due to nephritis," and in the latter place will also be found "coma due to diabetes," "coma due to brain trauma," etc.*

This system of grouping cases of similar nature has already proved a great convenience not only in certain statistical researches made in this hospital, but in preparing lists of patients who are to be asked to return for demonstration to students.

The next desideratum was felt to be flexibility,—that is, the system should be capable of later additions and alterations in the light of new knowledge. Every method which involves the use of numbers or other tokens in designating diagnoses is very ill-adapted to later alteration. We know of one hospital which embarked on a system of such a character years ago, and now finds that new diagnoses are often impossible to list, and that changing the system is prohibitive, since this would practically amount to copying every card for years back. For this reason numbers have not been used as a vital part of this scheme. A certain number of such tokens appear as guides to the eye, and for purposes of cross-reference from one section to another, and from the index; but these tokens are not used in the card catalog, and are likely to be changed with every new edition. As it stands, whole sections can be shifted if so desired, e.g., all the syphilis cards may later be changed from the section of infectious diseases to that of animal parasites, if new knowledge seems to warrant it.

Finally, as to practicality: It is to be taken for granted that the maximum of value cannot be attained without some complication of the system. We expect always to have a trained cataloger to do the work of filing, and anticipate that, in addition, one member of the staff will necessarily continue to give a half-hour or so a week to looking through the histories. It may be said, however, that this scheme has been found satisfactory in this hospital in two years of use by catalogers who were not previously trained, and, although some doubts arise and mistakes are made, these are probably not more frequent than with any other system.

An integral part of the scheme, following the tabulations, will be a very full index, containing not only the terms as used in the classification, but all possible synonyms, and even many terms which are refused standing, with cross-reference to the section where the approved terminology may be found.

No full description of the classification can be attempted in this place. It will be observed that the first seven main divisions are on the basis of etiology, viz. Infections, Animal Parasites, Constitutional Diseases, Poisons, General and Traumatic Effects of External Agents, and New Growths. To these are added No Disease and No Diagnosis. The remaining fourteen headings represent anatomical systems, under which as subheads will be found the individual organs and tissues, and under these, again, the appropriate diagnoses. With few exceptions the various heads and subheads are arranged alphabetically.

* Since the above was written, Miss Clark, the hospital record-keeper, has introduced the method of using a certain number of "dummy-cards" in the catalog. This will save much labor, even though it is to be applied only in such diagnoses as are rather common. Thus, under "Tuberculosis, Lungs" in the Infectious Diseases will be found in full all names and hospital numbers with this diagnosis; but under "Lungs, Tuberculosis" (Respiratory System) will be found a "dummy-card" with the notation "See Infectious Diseases, Tuberculosis, Lungs." Thus we still preserve the advantage of the double-listing.

ally, so that a diagnosis which is not given in the list can always be interpolated in its proper place. In this way we avoid the necessity for such a heading as "Unclassified."

I think that more than a word of apology is called for to justify the presentation of a new classification of this kind. The more one works with medical statistics, the more one is impressed with the great need for uniformity of nomenclature and classification throughout the country, or throughout the world. Examination of text-books of medicine shows that no two classify diseases by the same method, and often the same terms are used by two authors with widely different meanings.

Keenly as we felt the desirability of following some standard system, it seemed to us more and more evident that the optimum system had not yet been reached. The classifications which we considered most fully were the International List of the Causes of Death, the Bellevue Nomenclature, and those of the Massachusetts General Hospital, and Stanford University. Two of these have, it is true, been rather widely copied by hospitals throughout the country. At the same time we felt that none of them would do for us exactly the service we had in mind. For example, they would not allow, without modification, the entering of diagnoses in more than one place, a point which we considered of great advantage to the statistician. Also, none of them provided for the listing of subsidiary diagnoses to the extent which we wished, and none went far enough in the effort to correlate each lesion with its etiological basis.

In a general way we follow fairly closely the methods of the Bellevue and Massachusetts lists, only going farther in the same direction. Stanford has aimed at simplicity by furnishing only an alphabetical list of diagnoses without classification, with full cross reference to show the proper place for cataloging each term. The index of our system will give us much the same advantage, and we can still preserve those features mentioned above on which we lay so much value.

The justification of our wisdom in devising our own system will be in the way it works out, and in its reception by others. We believe the principle to be right, and hope that others will copy it. And if there are improvements to be made in it, we believe it will be found much more amenable to alteration and modification than the other schemes mentioned.

It should here be added that many other members of the Hospital Staff have generously co-operated, sometimes to the extent of drafting whole sections in which they were particularly interested. For the general plan the writer assumes the responsibility.

A few extracts from the system are here appended, to illustrate the general method.

CLASSIFICATION OF DISEASES FOR USE IN THE UNIVERSITY OF CALIFORNIA HOSPITAL

(Sample Pages)

Main Divisions:

- A. Infectious Diseases
- B. Diseases due to Animal Parasites.
- C. General Constitutional and Nutritional Disorders
- D. Poisoning
- E. General Results of External Agents
- F. Traumatic Effects of External Agents.
- G. New Growths
- II. No Disease
 1. No Diagnosis
 - I. Diseases of the Blood
 - II. Diseases of the Circulatory System
- III. Diseases of the Digestive System
- IV. Diseases of the Ductless Glands
- V. Diseases of the Ear
- VI. Diseases of the Eye
- VII. Diseases of the Female Generative System
- VIII. Diseases of the Locomotor System
- IX. Diseases of the Lymphatic System
- X. Diseases of the Male Generative System
- XI. Diseases of the Nervous System
- XII. Diseases of the Respiratory System
- XIII. Diseases of the Skin and Appendages
- XIV. Diseases of the Urinary System

A. INFECTIOUS DISEASES

(In every infectious disease, name all lesions found. In this list not all possible lesions can be given as subheads for each organism. In a few cases (*Gonococcus*, *Pneumococcus*, *Syphilis*, etc.) subheads are given in some detail. They may be used as examples for other infections where similar detail is not given. Avoid general diagnoses like *Actinomycosis*, *Syphilis*, etc., using these only when the disease is not localized.)

1. *Actinomycosis*
 - III.6 Liver
 - VIII.1 Bones
 - IX.2 Lymph-nodes
 - XII.4 Lungs
 - XIII. Skin and Subcutaneous Tissues
2. *Anthrax*
 1. *Septicaemia*
 - XIII. Skin and Subcutaneous Tissues
 - Malignant Pustule
3. *Bacillus Aerogenes Capsulatus* Infections
4. *Bacillus Mucosus Capsulatus* Infections
(For subheads see *Pneumococcus*)
5. *Blastomycosis* (Name part involved and lesions)
6. *Cholera, Asiatic*
 - a. Carrier
7. *Coccidioides* Infections
8. *Colon Bacillus* Infections
33. *Rabies*
 - a. Bite from rabid or suspected animal

- 34. Relapsing Fever
- 35. Rheumatic Fever Complex (In case organism is determined, list diagnoses under heading of this organism, with same subheads.)

II. 3.f Endocarditis

- Active
- Chronic Lesions resulting from

II. 5.a Pericarditis

- Fibrinous
- With Effusion
- Fibrous

IV. 6.k Thyroiditis

VIII. 4.b.i Infectious Arthritis, Rheumatic

5.j Myositis

XI. 1.h Chorea Minor

XII. 8.e Pleurisy

- Fibrinous
- With Effusion

XIII. Skin Lesions

36. Rocky Mountain Fever

37. Rubella

38. Scarlet Fever

a. Acute Nephritis

39. Sporotrichosis

40. Staphylococcus Infections

I. Septicemia

II. Circulatory System

3. Heart

f. Endocarditis

4. Mediastinum

a. Abscess

c. Mediastinitis

5. Pericardium

a. Pericarditis

7. Veins

b. Thrombophlebitis

III. Digestive System

2. Peritoneum

m. Peritonitis

6. Liver

a. Abscess

IV. Ductless Glands

V. Ear

2. Auricle

d. Perichondritis

4. External Meatus

e. Furuncle

f. Otitis Externa

6. Mastoid

b. Mastoiditis

7. Middle Ear

c. Otitis Media

II. DISEASES OF THE CIRCULATORY SYSTEM.

3. Heart

a. *Adams-Stokes syndrome

b. *Angina Pectoris

c. Aneurysm of Heart

d. Congenital Heart Lesions (unspecified)

i. Defective Interventricular Septum

ii. Open Ductus Arteriosus

iii. Open Foramen Ovale

iv. Pulmonic Stenosis

e. Disorders of the Heart-beat

i. *Arrhythmia (unspecified)

ii. Auricular Flutter

iii. *Bradycardia

*Use only as secondary diagnosis, giving cause of condition.

GUMMATOUS CERVICAL ADENITIS: ITS RELATION TO AND MISTAKEN DIAGNOSIS FOR TUBERCULOUS CERVICAL ADENITIS.*

By WM. PEARCE COUES, M.D., BOSTON,

Assistant Surgeon, Boston Dispensary; Instructor in Surgery, Tufts College Medical School.

IN all the vast amount of recent literature on syphilis, much of which pertains to the action of the recent remedies, salvarsan and neo-salvarsan, and the Wassermann technic, we find very little concerning syphilis of the cervical lymph glands. Gummatous cervical adenitis has been thought to be a comparatively rare manifestation, many syphilographers and those particularly interested in syphilis having seen but few cases. Where this form of tertiary manifestation occurs in cases obviously syphilitic, with other lesions or definite history, the condition is of interest; but the type which offers the greatest interest and difficulty of recognition is that which is the subject of this paper, that is gummatous cervical adenitis without other obvious signs of syphilis, mistaken in some cases and treated for tuberculous cervical adenitis, often over long periods of time without result. Several unusual and obscure cases of this nature I have been fortunate enough to recognize and study in the past few years and this has made a further study of the question of unusual interest.

A possible relation between tuberculosis and syphilis is well known to have occupied the attention of many students of both diseases for a considerable time; and we are constantly on the alert in cases of tuberculosis to prove or disprove a previous luetic infection. That numbers of cases of gummatous cervical adenitis are treated unrecognized as such, in the clinics and in private practice as well, is my belief; moreover, I do not think the condition is nearly as uncommon as has been supposed.

Mr. Jonathan Hutchinson¹ in his classic work on syphilis calls attention to the difficulty of making a definite diagnosis histologically between the two diseases in all cases. That the two processes may affect the cervical glands at the same time seems probable. Perhaps in such cases, where this is the only specific lesion recognized clinically, the gummatous process attacks glands previously tuberculous, perhaps small and latent, and is situated in such a location on this account; a "locus minoris resistentiae." That the converse of this is true at times must be admitted though it would seem less possible. Mr. Hutchinson's unique case was that of a "recurring chancre" or chancre redux; (tertiary lesion simulating chancre). It was excised and sent for examination; the pathologist reported typical tuberculosis except that no tu-

bercle bacilli were found. The section was shown to several expert pathologists who all pronounced it typical tuberculosis. The primary lesion in this case antedated the gummatous inflammation by five years. The pathologist despite the history, adhered to his opinion of tuberculosis. Sir Jonathan said in his remarks on this most interesting case: "After all, in these cases perhaps the two agencies are at work together, and that a latent tuberculosis modifies a more recent syphilis." On this subject, which is of such direct importance to us in this paper, Dr. Macloed, quoted by Hutchinson, has this to say: "The differentiation by the microscope between the granulomata of syphilis and tuberculosis is always difficult and in some cases impossible; for example, in the syphilitic gumma where a histological architecture may be present which resembles that of a lupus nodule in every detail with the exception of the presence of the tubercle bacilli."

This brings the following case to mind, also bearing directly on our subject though in the same general way as illustrating the difficulty of differentiating the two conditions, gumma and tuberculosis. A testicle was excised and was examined histologically by three competent pathologists. One pronounced it tuberculosis; one, sarcoma, and one, syphilis. After a time the other testicle became enlarged in exactly a similar manner and was cured by iodide of potassium.

In regard to the question of syphilis and tuberculosis, Burzi² quotes Nicholas, Favre and Charlet. In 45 out of 46 cases of syphilis they obtained a positive tuberculin reaction (intra-dermal) though clinically no symptoms of tuberculosis were found in the patients beforehand. It will be seen that when the pathological examination is at times so equivocal and perplexing, that the clinical picture between gumma and tuberculosis may be even more so, and especially where the process is in the cervical lymph glands. A careful history taken with a view to both tuberculosis and syphilis (congenital as well as acquired), is most important in arriving at a correct diagnosis of the condition, in cases of chronic cervical adenitis of a type to lead us to suspect one of these two conditions or both. Hawes³ has recently laid stress on the importance of a careful history in the cases of beginning tuberculosis and rightly laid stress on this over the physical examination. He urges that a history be taken with a view to syphilis in all cases. The history in cases where syphilis is suspected should be taken equally as carefully in cases of cervical adenitis. It is not enough to ask the common questions about miscarriages and stillborn children, but a more searching examination concerning collaterals and grandparents, if possible, should be obtained. It will often give precious information.

In passing now to a more special consideration of the subject we find, as stated previously,

* Read at the Pan-American Medical Congress, San Francisco, June, 1915.

that the literature on the subject of gummatous cervical adenitis is very scanty. A perusal of the *Index Medicus* from 1912 to 1913 and 1914 gave little information on this subject, though it is natural that some references may have escaped my attention. The most important, as well as interesting, communication on the subject is that of Wile*, though the latter part of our title, "The Relationship of the Condition to Tuberculosis of the Cervical Lymph Glands," is not brought out. Wile found a strikingly small number of cases in the literature and comments on the fact, as there is such an affinity for the lymph glands in the earlier stages of the disease. Why the deep lymphatics—chest, mediastinal, etc.—should be frequently invaded and the cervical glands escape so constantly, is a fact which well merits speculation.

In Fournier's analysis of 3429 cases of various tertiary forms of syphilis there is not a single instance of gummatous cervical adenitis (Wile). He estimated that the total of recorded cases was well under 100.

Virchow divided the process of gummatous cervical adenitis into three stages as follows: (1) Stage of simple irritation, during which the intercellular substance maintains a gelatinous consistency; (2) A medullary stage during which there is active cell proliferation, puriform softening of the tumor mass and softening of the intercellular substance; (3) The state of caseation in which active cell proliferation becomes less marked but in which the main cell types are connective tissue and granulation cells.

A brief résumé of Wile's cases is of interest at this time in connection with my own to be recorded later. A boy of 19 years received his initial infection only five months before the manifestation which is of interest to us. The syphilis was severe. Five weeks after infection there was some swelling of the glands in the left side of the neck; a supraclavicular gland swelled to the size of a plum; the skin was red and there was fluctuation. Aspiration gave a few drops of sero-purulent material. A few typical spirochetes were found with a dark field illumination. The glands ruptured by a pin point opening which enlarged, and typical gummatous ulcers developed. Five-tenths gram of salvarsan was administered once with marked local and general improvement; the patient had been under mercury before (salicylate grs. 3) every fifth day. In two weeks two small glands (unruptured) had diminished until they were of normal size and of the two ulcers the smallest one had entirely healed. There was gain in weight and marked improvement in health. Wile does not state whether there was any reason for supposing that there was a latent tuberculosis of the cervical glands in this case. From experience it would seem as if this was a perfectly possible reason for the process attacking the glands as it did. The age of the patient is favorable to such a supposition.

The following cases have recently come under my observation, illustrating this condition, and the effect of syphilis on what were pathologically pronounced tuberculous cervical glands:

CASE 1. M. G., a girl of eight years, was seen at the surgical clinic of the Boston Dispensary in my service as assistant surgeon, service of Dr. H. M. Chase, to whom I am indebted for the case. Patient first seen October 13, 1914, referred from the Children's Department for enlarged tuberculous (?) cervical glands. They had been enlarged three months. The patient had been treated one year before in the Surgical Department expectantly with that diagnosis. The history was given by the mother at the time as follows: Only child, no miscarriages, mother and father well. History of an old previous endocarditis. Examination showed a fairly well developed and nourished little girl. The cervical glands under the right lower maxilla were enlarged, the skin reddened and fluctuant. A large mass under the maxilla was firmly fixed, the chief site of disturbance. There were no obvious signs of inherited syphilis. There was a similar process less extensive on the left side of the neck. The tonsils were enlarged and the teeth were poor, there was a history of nasal obstruction. Cultures taken in the throat department showed various organisms, mostly staphylococci and pneumococci. The tonsils and adenoids were removed in the Throat Department and, at the same sitting, the glands were thoroughly opened, curetted and swabbed with iodine and drained. The specimen of gland debris was sent to the pathologist, Dr. F. B. Mallory, who reported that the glandular tissue showed on microscopic examination a process more suggestive of gumma than of tuberculosis. The Wassermann reaction at this time was negative. The Von Pirquet was also negative. After the pathologist's report was received, I put the child on mixed treatment which was later changed to hydrarg. cum creta and iodide. Improvement in the general condition was striking, locally there was some improvement in the glands. From a listless, tired little girl she began to be alert and interested. The glands were curetted again and much debris removed, the child was then given three injections of .2 gm. neosalvarsan (Dermatological Department). The effect was almost magical. In a few weeks the swelling in the neck had almost disappeared and the sinuses healed. In February, 1915, the child was discharged well, with a soft, supple neck, without obviously disfiguring scars. Of much interest are the following facts in connection with this case, ascertained later. The correct family history was as follows (first history by mother unreliable): The first child was stillborn. The third child died at four months. Twins, the fifth pregnancy, were premature and stillborn. The father later confessed that he had suffered from syphilis some years before, and had never been treated.

CASE 2. A. N. was seen at the Surgical Clinic of the Boston Dispensary, Dr. H. F. Day's service, in April, 1915. The history was as follows: The father died of cancer, the mother is living and well. There were four children; one died of measles. The child has had measles and pertussis. In February, 1915, operated on at the Boston City Hospital for tuberculous cervical adenitis. A radical excision of the glands on the left side of the neck was done.

Pathological report: Tuberculosis of the cervical lymph glands. Very soon after the operation the wound broke down and sinuses formed in the neck. Examination showed a well developed and nourished little girl. Skin and mucous membranes of good color. A puckered four-inch scar from old tuberculous gland on left side of neck and an abscess, probably tuberculous, on right side of neck. Lungs and heart negative. The Von Pirquet was positive. There were no obvious signs of inherited syphilis found on examination. April 26, Wassermann was positive. The neck was very slow in healing. After three weeks of specific treatment there was considerable improvement in the neck and the sinuses were nearly healed. One large soft mass above the left clavicle remained. No neosalvarsan has been administered. Child still under treatment.

CASE 3. Mrs. L. P., 45 years, was seen at the Surgical Clinic of the Boston Dispensary April 1, 1915. The family history was as follows: Mother died of "rheumatism" and "stomach trouble," the father is living and well. There were 11 children in the family, five sisters and five brothers. Two brothers and two sisters living. Six children died in infancy and childhood, some "passed away suddenly without cause." Patient has one son living and well, 14 years of age. As a child she was never strong, constant headaches, "poor blood" and easily run down. Married at 30. Only the child mentioned, and no miscarriages. One year ago in April there were enlarged cervical glands, bilateral, and in August they broke down and were incised and drained. They have been broken down and discharged pus from sinuses and ulcerated surfaces ever since. The glands in the neck were operated upon six different times, but no radical operation was done. The patient has felt very poorly of late. The diagnosis had been one of tuberculous cervical adenitis. On March 9, a positive Wassermann was obtained and four injections were then given of neosalvarsan at short intervals. Result: great improvement in neck condition, discharge lessened, sinuses healed, and though there is still a slight amount of indurated tissue in the neck, there has been great improvement. This is an example of probable true gumma of the cervical glands mistaken for tuberculosis in a possible congenital syphilitic.

CASE 4. Mrs. C. H., 28 years, was seen at the Surgical Clinic of the Boston Dispensary, October 27, 1913. There was a history of glandular swelling on the left side of the neck for 14 years. For the last two years the swelling had been painful. There was never any redness or fluctuation and there had been no sinuses or discharge. Some points in the general history are of interest. The patient had sought relief for the condition of the neck at various hospitals and dispensaries and of private physicians for years without benefit. The husband was living and well. The patient's father was dead, cause not ascertained. The mother is living and has diabetes. She has a positive Wassermann reaction. The x-rays of the mother's tibiae show a marked periostitis, and a brother of the patient, the mother says, has syphilis. Examination showed a well developed and nourished young woman. Throat and nose clear, teeth good, no obvious cause for the enlarged glands found on physical examination. There was no venereal history. On the left side of the neck there

is an irregularly prominent mass of hard discrete glands from filbert to walnut size, occupying the region immediately anterior and posterior to the sterno-mastoid, along its length, mostly in the lower and middle thirds of this space. The lower glands were the largest, just above the clavicle and slightly posterior. There was no other glandular enlargement found. Chest negative and abdomen negative. An x-ray of the chest showed numerous glands "peppered" well down to the diaphragm with some opacity about some of the glands. An x-ray of the tibiae showed a definite periostitis. The Wassermann reaction was negative. The child was examined and showed no obvious signs of inherited disease. On November 5 the patient was put on intensive specific treatment, mercurial inunctions and iodide. The effect was striking. After three weeks, the glands were softer and smaller and the neck could be moved better. The patient's general health which had not been good was greatly improved. By January the glands were nearly gone, only one of large size remaining. In April, 1914, I excised one of the small glands for diagnosis under local anesthesia. The pathologist reported typical tuberculosis of a cervical lymph node. A short time after the operation the incision broke down *without suppuration*, the wound taking on a typically gummatous character, which healed promptly with a good scar under mercurial ointment locally. In January, 1915, the patient was seen again. The glands could hardly be felt and there was no discomfort or pain. The neck was soft. General condition good. There is a small sessile growth projecting down from the left side of the soft palate. Patient refuses its excision.

Fasal,⁵ quoted by Wile, says that the topography of the gummatous adenopathies seems to be dependent on the occurrence of the earlier cutaneous and mucous membrane lesions. This would seem plausible if we accept the modern view of spirochetal permeation.

Up to 1912 only two cases of this condition were reported in the American literature. Most of the cases reported were those occurring at the same time as other tertiary lesions. Wile says that, in his opinion, in the state of our knowledge of the different granulomata's reactions to mercury and iodide, great caution must be exercised in making a positive diagnosis of syphilis on the clinical signs of improvement, without other data and examinations to judge by. We must also bear in mind the opinion of Macleod stated earlier in the paper, and that of Nicholas, Favre and Charlet concerning the extreme difficulty and at times impossibility of arriving at a correct diagnosis microscopically, between syphilis and tuberculosis.

Cases of cervical adenitis supposed to be tuberculous, yet not quite characteristic, should be regarded as possibly gummatous, and careful study with all the means at our command should be made to prove or disprove this supposition definitely. It has been proved that, after all, the clinician must fall back on consideration of the case with an exhaustive history pertaining to possible syphilis, to arrive at a correct diagnosis.

LOCAL ANESTHESIA IN THE RADICAL CURE OF HERNIA.

BY ALBERT EHRENFRIED, M.D., BOSTON,

*Assistant Visiting Surgeon, Boston City Hospital;
 Junior Assistant Surgeon, Children's Hospital;
 Surgeon, Boston Consumptives' Hospital.*

[From the First Surgical Service, Boston City Hospital.]

DURING the past few years, under the leadership of Braun of Zwickau, the use of local anesthesia has been popularized and its field broadened. In a tentative way the method has been applied in the German clinics to practically every operation listed in the text-books. As a consequence, there has been a definite reawakening of interest in the subject in this country, an interest which has lain dormant since the brilliant work of Corning, Crile, Matas and Cushing, which followed close upon the introduction of cocaine in the eighties.

As a result of experimentation and of recorded experience, the practical applications, and the limitations of the method as well, can now be rather definitely stated. Certain fields exist where general anesthesia will still be preferred, for instance, the peritoneal cavity and the brain; not that local anesthesia cannot be and has not been successfully employed in these regions, but that the advantages of the method are on the whole overbalanced by the complexity of the technic, the uncertainty of the results, and the strain on the patient.

One field in which local anesthesia may be employed with considerable satisfaction, according to my experience, is in the operative treatment of inguinal hernia. It has recently happened that within one week three patients with inguinal hernia, in whom general anesthesia was contra-indicated, came under my care, the hernia being recurrent in two instances. Briefly summarized, their histories are as follows:

CASE 1. W. H. D., 62, no occupation, entered the Boston City Hospital July 15, 1915. Has had a massive right inguinal hernia for 14 years, during which period has worn a truss constantly. Lately pain has been troublesome. Desires operation on account of pain.

Obese. Blind from infection following injury. Crackling rales at left base. Heart enlarged outward, with loud musical systolic murmur transmitted to axilla. Urine shows renal elements.

Local: Easily reducible right inguinal hernia size of hen's egg when recumbent. Large fat pad, with calloused skin over area size of palm.

Operation, under local anesthesia, July 17. Four inch skin incision. Aponeurosis divided over canal, and freed back. Margin of conjoined tendon and Poupart's ligament developed ready for suture. Sac found and dissected free without disturbing cord. Ring takes three fingers. Sac sewed off, stump transplanted under transversalis and internal oblique. Conjoined tendon sewn to Poupart's over cord with four mattress sutures of kangaroo. External oblique closed with interrupted sutures of 1 chromic. Fat layer carefully approximated with same. Subcuticular silk-worm-gut. Cunningham swathe.

Temperature was normal during entire stay in hospital. Patient suffered no discomfort and convalescence was uneventful. On August 2 head-rest was allowed, and patient was discharged August 6, with wound solid and no bulging on cough.

CASE 2. Walter C., grocer, 47, entered the Boston City Hospital July 21, 1915. Was operated in this hospital for appendicitis with peritonitis 10 years ago. Developed hernia in scar, which was repaired two years later. Had second attack of appendicitis, reoperated three years later. "Chronic bronchitis" for years. Has had hernia in scar for seven or eight months, made worse by nagging cough. In this period it has been incarcerated twice, but each time reduced by physician. Is planning to go south in the early fall, and desires operation on account of danger of strangulation.

Poorly nourished. Signs of quiescent phthisis at right apex. Heart sounds distant and of poor quality.

Local: Wide bulging scar, impulse on cough.

Day after entrance, while walking down ward, collapsed. Seen in consultation by Dr. Robey, who found nothing to contra-indicate operation under local anesthesia, which was undertaken.

July 22, ellipse including scar excised, and much subcutaneous scar tissue dissected away. Aponeurosis of external oblique recognized, and freed from scar mass. Poupart's ligament developed, as well as edge of conjoined tendon. Small sac tied off without disturbing cord. Four mattress sutures of kangaroo tendon placed. Closure as in preceding case.

Convalescence agreeable and uneventful except that on fourth day patient had a coughing spell with rise in pulse and temperature. "Like attacks I used to have," which subsided in a few hours. Otherwise pulse and temperature normal. Head-rest August 10. Discharged August 13, with wound healed and no impulse to cough.

CASE 3. F. A. P., lawyer, 79, entered the Boston City Hospital July 21, 1915. Always well. Nine years ago operated for left inguinal hernia in this hospital. Two years ago right side operated by private surgeon for similar condition. One year ago attack of "cerebral hemorrhage," unconscious for one week. Comes in for recurrence of hernia on right. Painful. Cannot wear a truss. Earnestly desires an operation.

Senile, but well preserved and mentally acute.

General physical: Negative except for heart which is irregular in action, with presystolic murmur at base. Pulse high tension. Urine shows renal elements.

Local: bulging in scar in right groin.

Operation under local anesthesia, July 23. Scar excised. Fascial planes developed. Lower half of former repair found to be holding beneath cord. No sac found, but merely wide bulge of peritoneum of upper half. Conjoined tendon sewed over cord in Poupert's in upper half of wound with mattress stitches of kangaroo tendon. Closure as in preceding cases.

Convalescence agreeable and uneventful. Headrest August 10, up in chair two days later, and discharged August 14. Wound healed. No bulging on cough.

TECHNIQUE.

In the first patient a preliminary hypodermic injection of morphine-atropine was administered as a routine measure before my order to the contrary had been transmitted. The other two cases had no sedative before operation, and required none. In none of the cases was an opiate required at any time after operation.

With the instrument kit there was boiled up a glass jar of 150 c. c. capacity, to hold the anesthetic solution. Two syringes were put in a glass slip-joint syringe of the Luer type, holding 5 c. c., with two ordinary small hypodermic needles, and a slip-joint Record syringe holding 20 c. c., with two needles of larger diameter $2\frac{1}{2}$ inches long, having rather obtuse points.

The solution used was half per cent. novocaine, made up in distilled water, and previously sterilized for 20 minutes in the autoclave. One hundred cubic centimeters of this solution were poured into the sterile jar, and 10 drops of 1-1000 adrenalin added. This solution can be used freely, it having been found that more than 250 c. c. can be injected without toxic effect. Actually, in this small series, the amount employed averaged a little over 50 c. c. per patient. For operative purposes it may be said that cocaine has been entirely discarded for this derivative, which has the advantages of comparative non-toxicity and sterilizability.

Everything was made ready in the operating room before the patient was wheeled in on the table. The skin preparation (benzine-iodine-Harrington's alcohol) was done without fuss, and the patient draped. The eyes were not covered. When it can be done conveniently it may be better to prepare and drape the patient before bringing him in.

Immediately, using the Luer syringe, the line of incision was injected by the endermic method of successive wheals. In the two recurrent cases a wide ellipse was outlined, to include the scar. No preliminary freezing of the skin was employed. If consideration is used in making the first injection, the others can be made rapidly and without pain, and a small syringe used endermically will go a long way.

Braun has given up the method of anesthetizing the skin first, on the ground that it is unnecessary. He makes one wheal only, for the passage of the long needle, through which he in-

jects the subcutaneous tissue along the line of incision. But to completely anesthetize the skin by this indirect 'conduction' method requires a considerable quantity of solution, penetrating to some distance on either side of the proposed line, and necessitates a certain wait for its accomplishment. I believe it to be true that if the line of incision is first injected endermically, the surface anesthesia will be more assured, much less solution will be required in the subcutaneous tissue, as a consequence of which there will be less distortion of the field, and the incision can be started without waiting as soon as the injection is completed.

The skin injection done, the long needle of the Record syringe was introduced through the upper end of the line of wheals and passed downward its entire length in the subcutaneous tissue, and while being withdrawn, a small amount of solution was introduced. Then without withdrawing it from the skin puncture, it was re-introduced at a deeper level several times at varying angles along and to either side of the canal. The bluntness of the needle was a safeguard against perforation of vessels, vas or peritoneum. The syringe was then refilled, and a puncture made at the lower end of the incision, and the cord and the region of the external ring similarly infiltrated. In the two cases of recurrent hernia the punctures were made not at the upper and lower ends of the incision line, but at the middle of the two lines forming the ellipse.

This having been expeditiously accomplished, it was found that the skin was insensitive, and at once ready for incision. The operative technique was that which seemed indicated by the condition found. The dissection, which had to be quite extensive in the recurrent cases, was done almost entirely by the blunt method, using the unopened dissecting scissors,—a procedure which was distinctly favored by the tissues being ballooned with fluid. Gentleness was used in all necessary manipulations, unnecessary instruments were kept out of the wound, and retraction was done largely with the fingers. There was practically no hemorrhage, owing partly, no doubt, to the fact that the vessels were avoided by the method of blunt dissection employed. The few bleeders met with were seized with mosquito snaps and tied off at once with fine catgut.

The first injection usually sufficed to carry us down to the cord and the peritoneal sac without any evidence of discomfort. A few cubic centimetres injected here, the amount depending on the manipulation necessary in the individual case, effectually controlled any sensitiveness. The deep stitches were placed well into Poupert's ligament without causing pain, and in closing up, no further injections were required.

The operative time averaged 50 minutes from the first injection to the completion of the subcuticular closing stitch. The patients went back to the ward in good humor, somewhat tired

from the restraint of maintaining the one position on a hard table, but ready for a lunch, and expressing satisfaction at the simplicity and painlessness of the procedure. Being men of some intelligence, and having each been operated on before, they were in a position to make comparisons.

CONCLUSIONS.

Novocaine offers a simple and satisfactory means of inducing anesthesia for the radical cure of inguinal hernia, even in complicated cases. The technic adds something in the way of difficulty to the surgeon who is not accustomed to the use of local anesthesia, but the advantages to the patient are sufficient to compensate for any extra care or effort required. It should be the method of choice in cases where contra-indications to general anesthesia exist, and it should be used in any ordinary case if the patient desires it.

STUDIES IN SPEECH DISORDER.

No. 4.*

ELIMINATION OF VOICE DEFECTS FOLLOWING ADENOID AND TONSIL OPERATIONS.

BY WALTER B. SWIFT, M.D., BOSTON.

*In Charge of Voice Clinic, Boston State Hospital,
Psychopathic Department, Boston.*

BEFORE indicating the treatment sometimes necessary to perfect vocal expression after adenoid and tonsil operations, it will be *à propos* to say a word about tonsil overgrowth, adenoid obstruction, and the sounds thereby made impossible of production; that one may see just how vocal faults of articulation arise, how they become fixed habits, and how the vocal expert is needed to round out again and perfect the previously normal vocal execution.

The group of glands known as the adenoids, tonsils and the lingual tonsil form what laryngologists term the tonsillar ring. The adenoids are located above the uvula, and their overgrowth obstructs the passage of air into the nares. It naturally follows that when obstruction is complete, nasal breathing becomes impossible and any vocal utterances that require an open nasal passage for their production are no longer possible of execution. This vocal failure of execution may be of two forms, depending upon whether the patient's obstruction came before or after the learning of those utterances

that require the open nares. If the obstructing growth occurs before articulation has become set in its execution in the mind and the expressing mechanism, then, as long as the obstruction lasts, there can be neither memory nor experience of the proper vocal expression. If, on the other hand, the occluding obstruction has started its growth later in life, after vocal execution has become ingrained in its memory and vocal mechanism of execution, then during the obstructive period there still lasts, though becoming more or less dim as time passes, a memory for those previously executed vocal elements. The throat specialist sees the material obstruction, less worthy of note to him is the vocal occlusion; he weighs the dangers of the consequent mouth breathing as a means of receiving infection; he sees the general constitutional effects,—anemia, stunted growth, perhaps malnutrition; and, if the case has been of long duration, the retardation in the studies of the school, play a considerable part in leading the laryngologist to recommend operation. Not long ago a complete recovery from all the above-mentioned symptoms was promised, and often in glowing terms, but of late years experience has led the throat men to be more conservative. They have found that even after operation one or more of the above symptoms may persist, and among the most frequent are the mental backwardness and the faulty vocal execution.

Then diet, fresh air and exercise are recommended, which, of course, fail to reach the seat of the trouble, and these mental and vocal sides of the situation persist too often untreated thereafter.

What, then, are the vocal defects that persist after adenoid and tonsil operations; how shall their elimination be effected, and who is fitted to engineer that elimination?

The vocal defects resulting from nasal or laryngeal obstruction gather about the execution of "m," "n," "ng" and "k" and "g," and some of the vowels are changed slightly. The vocal execution of a normal "m" and "n" require closed lips, free buccal cavity and open nares. The normal "ng" requires closed lips, closed buccal cavity and open nares. Manifestly then, when the nose is blocked the sounds of these executions change, and this change is what is known as nasality.

With "k" and "g" the situation is slightly different. These sounds are made thus: "k" by an air explosion made when a closed larynx is suddenly opened by lowering the back of the tongue; "g" by the same technic as for "k," with the simple addition of vibration in the vocal cords. When tonsils and adenoids occlude these passages, "k" and "g," a nasal element is added to their usual sounds, not, however, quite so marked as when "m" and "n" are involved, but enough so to call it an approach to nasality.

Thus with overgrowths in these resonant chambers the patient is forced into enunciations that persist as long as the occlusions persist, and

* No. 3, see BOSTON MED. AND SURG. JOUR., Nov. 11, 1915.

this explains why they frequently continue after operations. The reason is because either never having learned the proper articulation or being so long forced into a faulty one, these continue on beyond the period when the obstructing tissue is removed.

From the above cases one sees there is quite a variety of defect that accompanies and follows the tonsil and adenoid hypertrophy. The treatment varies much with every case. Even some with the same defects have to be approached differently from others because of their different dispositions, and others differently merely because their ages differ. Otherwise it consists in reteaching vocal expression through imitation and didactic instruction, varying according to age and disposition. Much more than this it is difficult to put into the printed word, as it is more or less a matter of sound production and sound imitation, which obviously must be heard and cannot be printed. However, it sometimes takes a good study to determine by sound just what the present faults of utterance are, and still more ingenuity to instill the proper execution.

Summary. Operations for adenoids and tonsils often fail to relieve habits of faulty articulation and consequent school retardation. Vocal drill by one trained scientifically in speech disorder is the surest method to secure speedy permanent relief, in that perfect articulation that makes possible an easy enjoyable conversation.

Book Reviews.

Modern Medicine. Its Theory and Practice. Edited by SIR WILLIAM OSLER, Bart., M.D., F.R.S.; and THOMAS McCRAE, M.D. Vol. V, Diseases of the Nervous System—Diseases of the Locomotor System. Second edition, thoroughly revised. Philadelphia and New York: Lea and Febiger. 1915.

The fifth and last volume of this well known system has just appeared in its second edition. The contributors are essentially the same as in the first edition. The larger part of the volume, some eight hundred and seventy pages, is devoted to the discussion of diseases of the nervous system—some eighty pages suffice for the discussion of the various diseases of the locomotor system that have not been treated elsewhere. Dr. Harvey Cushing contributes an admirable chapter on "tumors of the brain and meninges" and another one on "hydrocephalus." Dr. Bernard Sachs has an excellent discussion of "syphilitic disease of the central nervous system." It

is needless to say that all the contributions bear the stamp of authority. The revised second edition of the fifth volume completes what is probably the best system of modern medicine in the English language.

Reports from the Laboratory of the Royal College of Physicians, Edinburgh. Edited by J. J. GRAHAM BROWN, M.D., and JAMES RITCHIE, M.D. Vol. xiii. Edinburgh: Oliver and Boyd. 1915.

This volume continues the valuable series of reports of researches from the laboratory of the Royal College of Physicians at Edinburgh, and represents the contributions of workers made during the years 1913 and 1914. In the preface acknowledgment is given of the generous financial support received by the laboratory from the Carnegie Trust for the Universities of Scotland. The volume consists of a series of thirty-two articles by eighteen authors, reprinted from various medical journals. These papers are grouped under the headings of protozoology, anatomy, biological chemistry, pathology and bacteriology. Particularly to be noted are the contributions by Meiklejohn on the topography of the intracardiac ganglia and on the innervation of the nodal tissue of the mammalian heart. The volume is abundantly illustrated. Particular attention should be called to the series of thirty cuts representing Fraser's and Dickie's reconstruction model of the middle and inner ears. The volume, like those of the Rockefeller Institute for Medical Research, is an important medical contribution to the advancement of science.

Some American Medical Botanists Commemorated in Our Botanical Nomenclature. By HOWARD A. KELLY, M.D., LL.D. Delivered as a lecture before the Medical Historical Society of Chicago, 1910, and before the University of Nebraska, Oct. 16, 1913. Illustrated. Troy, N.Y.: The Southworth Company, 1914.

This book contains the subject matter utilized for lecture purposes by the author, himself a medical botanist of no mean calibre. All such efforts to awaken the interest of the busy practitioner in outside subjects are praiseworthy, particularly when they contain, as this book does in high degree, useful information carefully gathered and presented in readable fashion. Starting out with the life work of those physicians for whom flowers have been named, as the gardenia, wistaria and claytonia, the author gradually included thirty excellent and adequately illustrated biographies.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

THE MIDWIFE VERSUS THE PREGNANCY CLINIC.

As leading articles in this issue of the JOURNAL we are glad to present two papers on the midwife problem by two Boston physicians, representing two radically different modes of regarding and undertaking the solution of this important question. The first article, by Dr. A. K. Paine, reaches the conclusion that in view of the obvious deficiencies of training in obstetrics in this country, the best method of meeting the needs of the situation is to adopt the midwife system of Europe, placing it, however, under suitable regulation and providing adequate training for those who are to undertake this work. The second article, by Dr. James Lincoln Huntington, on the other hand, after pointing out the inherent evils of the midwife and the undesirability and impracticability of such training, describes the work of a well-

equipped pregnancy clinic, contrasting the merits of such a system, in conjunction with a lying-in hospital, with the disadvantages of the midwife method.

The midwife problem has been amply discussed in previous issues of the JOURNAL, both editorially and by authors of original articles on this subject. In the light of the argument presented by the two new papers under consideration, we see no reason to modify the attitude hitherto taken by the JOURNAL in condemnation of the midwife and in approbation of the pregnancy clinic system. On the contrary, it seems that the results already demonstrated in the work of the pregnancy clinics at the Boston Lying-in Hospital, at the Maverick Dispensary, and at the Peter Bent Brigham Hospital, to mention some of those in this city alone, demonstrate the superiority of an organized system of pregnancy supervision and out-patient care by competent young physicians and medical students under the supervision of a lying-in hospital staff. The education and regulation of midwives is a difficult and expensive matter. If adequately carried out, it involves not only a greater burden on the community, but the maintenance of a pernicious dual standard of obstetric competence. If not efficiently carried out, or if not carried out at all, it leaves the untrained, or ill-trained midwife as a perpetual menace.

The difficulties of maintaining and administering an efficient midwife system are illustrated by the experience of European communities where this has been attempted. The experience of Scotland, a large number of whose leading physicians have recently petitioned for the passage of a midwife bill for that country, can hardly be cited as an instance in point, since the circumstances of war now prevailing in that country, whereby a large number of medical practitioners have been called to the front, are not to be compared with those obtaining in a country like our own, or indeed, in any peaceful community in which the medical and nursing professions are abundantly filled.

The evils of the midwife system are recognized not only by the profession, but by many among the laity. In a recent issue of the *Chicago Tribune* there appeared an editorial comment on the midwife question, which summarizes in part as follows the comparative obstetric situation in Europe and in the United States:

"The midwife is a product of the Old World, and it is among recent arrivals from Europe that

she plies her trade in Chicago. While there was, and still may be, room for the limited experience and the imperfect knowledge of the midwife in the peasant communities of Russia, Poland, or Galicia, there should be no room for a midwife in Chicago. In the peasant communities of the Old World one has to travel frequently twenty-five or thirty miles to obtain the services of a physician. To make such a journey by wagon—and railways are scarce in such regions—often may mean death to the patient. There the crude obstetric knowledge and experience of a midwife may save a life.

"In Chicago, where the patient is separated from the physician by the space of but a street car ride or an automobile run, the ministrations of a midwife cannot be excused on the grounds of expediency. Her experience counts for naught in comparison with the physician's training. The most intelligent of midwives knows next to nothing about anatomy. No matter how clean she keeps herself she is ignorant of the laws of sepsis. She is useless or worse in the sickroom. Where the patient's condition is precarious the midwife is herself compelled to call a physician in order to save her own neck. Where, on the other hand, the condition of the patient is normal, the ministrations of the midwife carry with them at all times a menace of infection.

"The argument in favor of midwives is that they are economical, that they are used in families who cannot afford a doctor. That is no argument. Such cases should be provided for at hospitals and dispensaries. Another defense of the midwife is based on the ground that some women will submit only to the ministrations of a woman. But this defense, likewise, does not hold water. There are plenty of excellent women physicians in this city that can be called in just such cases.

"A ban upon midwives will result in hardships upon a number of individuals, who are now finding midwifery a profitable occupation. But the suppression of the irresponsible practice of medicine and obstetrics by ignorant women will do incalculable good to the community at large."

This editorial is of additional significance, coming as it does from the American city which has the highest percentage of midwife attendants. According to a recent report of Dr. Henry G. Ohls of the Chicago Health Department, there are in that city about 500 midwives who attend over 43½% of all births occurring in that city. In New York City there are 1300 midwives who attend 40% of the births. In Pittsburgh, 31% of the births are attended by midwives and in Philadelphia 21%.

In conclusion, it seems that while, under the conditions of life in many European and Asiatic communities, the midwife is, perhaps, an inevi-

table evil, her existence is inconsistent with the methods and ideals of civilization and of medical science in this country. This was the conclusion also reached at the recent conference on infant mortality at Philadelphia, noted in another column of this issue of the JOURNAL. That the midwife system has been introduced chiefly as a result of our large alien immigration is a misfortune; that it should be permitted to continue, or to be extended among our native communities seems not only undesirable, but a menace to the ultimate higher development of our civilization and science. It is not to be expected that the midwife system as it now exists should be abrogated unless it is to be replaced by a system in every way superior and preferable. As such a substitute, the pregnancy clinic system co-ordinated with a lying-in hospital seems wholly superior to a system involving the recognition, training and registration of the midwife as a permanent factor in the medical practice of this country. The midwife in America is an anachronism and an anomaly, and should not be tolerated, but eliminated as speedily as an adequate and efficient substitute system can be developed for the obstetric care of all classes of the community.

AN IMPORTANT PUBLIC HEALTH SERVICE.

IN last week's issue of the JOURNAL we noted the appointment of Dr. Haven Emerson to succeed Dr. S. S. Goldwater as commissioner of health of New York. The retirement of Dr. Goldwater from this important position marks the conclusion of a very valuable and notable service in the cause of public health. Although this service has lasted less than two years, there have been made during this brief time important advances in the activities, administrative methods and scope of purpose of the department. Dr. Goldwater accepted this position at great personal sacrifice, and, in relinquishing it to return to his duties as director of the Mt. Sinai Hospital, carries not only the gratitude and admiration of the community which he has served, but the appreciation of the medical profession for the nature of that service.

A recent issue of the *New York Evening Post* has expressed effectively the intelligent public opinion of Dr. Goldwater's work and of his methods in accomplishing it.

"The energy which Dr. Goldwater has put into his conduct of the Health Department, an energy which has seemed inexhaustible, has been manifested in two distinct ways, and it is difficult to say in which of the two it has been more remarkable. While the public has been hearing, at brief intervals throughout his incumbency, of extension after extension in the scope of the department's activities, it has had fully as much reason to be impressed with the unyielding vigor that he has put into the enforcement of the health laws and of the orders of the department. On the first head, a glance at the summaries of the department's activities issued at the close of last year, and at the close of the first half of the present year, is sufficient to remind us how much has been done. We can name but a very few examples, out of a large number. There have been established a Bureau of Public Health Education, a Division of Industrial Hygiene, a self-supported system of meat inspection—the cost being met by the assessment of firms selling the goods. We all remember the energetic sally of the department into a new field when it undertook to put a stop to avoidable over-crowding in the subways and on surface cars. The inspection of dairy farms had previously been left to the milk commissions of the various county medical societies; the department, feeling that it was responsible to the city for the safety of the entire milk supply, has instituted periodical examinations of these farms and their products. These, as we have said, are but a few samples of the extension of the department's work; and it ought to be added that, so far as we have noticed, every one of the multitude of extensions has been accomplished, not by the use of additional money, but by such effective improvement of organization as to make the new work possible without increase of expense.

"Of even greater interest than the undertaking of new work is the vigor, intelligence, and determination which have evidently been put into every feature of the department's activities. Any one who regularly sees the weekly bulletins of the department must be struck with the live character of their contents. They are full of interest, and cannot fail to be of great practical utility; especially now that the number issued has been increased to twelve thousand, so that they are sent regularly to every practicing physician in the city. The vigor and success with which the campaign of the department against patent medicine evils has been carried on during the past few months is perhaps the most recent reminder of the spirit in which it is doing its work. And all along the line, it has come to be known that when the Health Department says a thing it means it, and that its force is so well organized as to enable it actually to do what it either promises or threatens."

On November 6, at the conclusion of Dr. Goldwater's term of office, a testimonial dinner to him was given by officials of the Health De-

partment of New York City. Among the speakers who expressed their appreciation of the work of Dr. Goldwater as Commissioner of Health were Commissioner Emerson, Dr. Charles F. Bolduan, Dr. Matthias Nicoll, Jr., Assistant Corporation Counsel William J. Millard, Dr. Charles B. Slade, Dr. William H. Park, Dr. S. Josephine Baker, Dr. Robert J. Wilson, Dr. L. I. Harris, and Mr. Ole Salthe. Dr. Goldwater, in response, outlined his conception of the work of a modern health department as one which, more than ever, would serve for the maintenance of good health rather than temporize with attempts to cure ill health.

A service such as Dr. Goldwater's, though brief, is of importance in the history of the development of public hygiene and of preventive medicine in this country, since it contributes to the establishment, not only of administrative methods, but of a standard of achievement, purpose, and progress, that will be of value to the future, as it has been of benefit in the past and present.

RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS IN OCTOBER, 1915.

THERE has been an increase in the number of cases of communicable diseases in Massachusetts for the month of October. This increase is an annual event. It is always coincident with the opening of the public schools. In comparison with the same month last year, the total of communicable diseases reported to the boards of health shows considerable increase. An analysis of the reports shows that the greater prevalence of whooping-cough in various parts of the state is largely responsible for this increase.

Whooping cough has been prevalent in many parts of the state. The difficulty of early diagnosis and efficient quarantine in this disease is largely responsible for its continued spread. Some practical work is being done by the New York City Department of Health as to the use of a vaccine for this disease. Results of their studies will, no doubt, soon give out some important facts to help us in our control of this infection. While there have been no epidemics in any particular city or town, in a few places it has been particularly prevalent. Among those places may be mentioned Cambridge, Province

town, Chelsea, Lawrence, Waltham, Natick, Northampton and Whately. Springfield has been having a considerable number of cases for several months, but they seem to be decreasing.

The diphtheria situation is of interest. A comparison with October, 1914, shows that there are about the same number of cases this year. One fact, worthy of note, is that they do not seem to be so fatal this year. The fatality rate last year was 6.7 and this year 3.8. While this is gratifying, yet it is no insurance that the infection may not become virulent at any time. There have been no marked epidemics of diphtheria during the month. However, the disease has been particularly prevalent in the following cities and towns: Attleborough, New Bedford, Haverhill, Malden, Rockport, Saugus, Lawrence, Lowell, Waltham, Fitchburg, Hudson, Leominster, Shirley and Agawam.

The spread of diphtheria seems to be definitely along certain lines. The comment by one of the District Health Officers in reporting a diphtheria investigation seems to apply almost generally to the state. He says, "This outbreak shows the usual cycle of unrecognized cases with the physician called late, the extension of the disease by contact with others in the immediate neighborhood, and the spread of the disease in the school." An analysis of the reports coming to the department show that this seems to be true in almost all of the considerable outbreaks reported. The common practice of closing the schools is not so effective as keeping them open, when adequate medical inspection of the schools can be made daily. Our more exact knowledge of the disease and more scientific use of the culture method, plus the application of the Schick test, should enable us to work out a more efficient procedure in controlling this disease.

The typhoid fever situation continues to be favorable. As usual, there is some increase over September. In this disease the fatality seems to be slightly higher than for the same month last year. The following cities and towns have had more typhoid fever than usual: Pittsfield, Somerville, Lexington, Quincy, Bridgewater, Northbridge, Chelsea and Lowell.

Two particular foci are of interest. Northbridge has had an epidemic of 18 cases, in which the result of the investigation seems to point to the milk supply of one man. However, in this outbreak, there is a possibility of water-borne infection. For fire purposes polluted water is used in the domestic water supply.

Mansfield continues to have some cases of typhoid fever. The beginning of the prevalence of typhoid fever in this town dates back about two years. As in the former epidemic, the mode of transmission is probably milk. The evidence seems to point to the infection coming from a carrier of 45 years' standing.

MEDICAL NOTES.

AMERICAN ASSOCIATION FOR STUDY AND PREVENTION OF INFANT MORTALITY.—The sixth annual meeting of the American Association for Study and Prevention of Infant Mortality was held at the Bellevue-Stratford Hotel in Philadelphia Nov. 10, 11, and 12, under the presidency of Mr. Homer Folks of New York. Among those present from New England were: Mrs. William Lowell Putnam of Boston, Prof. John L. Morse, Drs. Richard M. Smith and J. Herbert Young of the Department of Pediatrics in the Harvard Medical School. Mr. George Bedinger and Mr. Charles Mason represented with Dr. Young the Boston Milk and Baby Hygiene Association. Dr. Buckingham of Boston, Dr. A. B. Emmons, 2nd, of Boston, Dr. J. L. Huntington of Boston, Dr. Harold J. Everett of Portland, Me., and Mr. Richard Borden of Fall River, were also in attendance.

In the section of Obstetrics papers were read as follows: "The Education, Licensing, and Supervision of the Midwife," by Dr. J. Clifton Edgar of New York; "Is the Midwife a Necessity?" by Dr. J. M. Baldy, of Philadelphia; "Progress Toward Ideal Obstetrics," by Dr. Joseph B. DeLee of Chicago. These authors all agreed on one point, namely, that all efforts should tend toward the eventual elimination of the midwife.

At the conclusion of the meeting very radical resolutions were introduced, aiming towards the recognition of the midwife by legislative means. This was referred without discussion to the Committee on Resolutions to report back to the Executive Committee of the Association at its next meeting in January, 1916.

NATIONAL MEDICAL EXAMINATION DAY.—In a plea for every man and woman in the United States of adult age to join in a movement for annual or other periodic medical examination of themselves, which will be initiated on December 8, the National Association for the Study and Prevention of Tuberculosis presents figures in a Bulletin issued recently which show that practically 100% of the supposedly well people of the United States over 30 years of age have some physical defect or impairment. About 70% of these impairments are of a more or less serious nature. There are besides about 30% of defects of a minor character.

The figures which the National Association

presents are based upon the careful studies recently made by the Life Extension Institute among two highly specialized groups of people, the first group consisting of workers in the Ford Motor Company of Detroit, and the second group consisting of employees of commercial houses, banks and trust companies in New York. The records of these examinations show that practically none of those examined,—men and women—are normal in the strict sense of the word. Another striking fact in the examination is that only 10% of those who were impaired were aware that there was anything the matter with them. This fact alone, the National Tuberculosis Association points out, is sufficient to make every man and woman in the United States give careful consideration to the necessity for at least one physical inventory of the entire body a year.

The largest group of more or less serious impairments discovered were those showing sugar, albumen or casts in the urine. More than 45% of the above-mentioned groups showed defects of this nature. In the same groups about 23% showed abnormal blood pressure, while nearly 27% showed combined disturbances of circulation and kidneys. Organic heart disease, thickened arteries, lung trouble leading to possible tuberculosis, nervous affections, digestive troubles and venereal disease were among the other impairments discovered, practically all of which had escaped the notice of the individuals examined.

During Tuberculosis Week, which will be celebrated throughout the United States from December 6 to December 12, a national medical examination day will be observed on December 8. Groups and individuals will be urged to make arrangements for physical examination on that day. A circular describing in detail how the advantages of medical examination day may be obtained and indicating certain physical impairments which everyone should look for, will be sent on request from the office of The National Association for the Study and Prevention of Tuberculosis, 105 East 22nd Street, New York City.

PREVALENCE OF MALARIA, MENINGITIS, PELLAGRA, POLIOMYELITIS, SMALLPOX AND TYPHOID FEVER.—The weekly report of the United States Public Health Service for October 29 states that during the month of September, 1915, there were in Virginia 2665 cases of malaria, 21 of cerebrospinal meningitis, 64 of pellagra, 17 of poliomyelitis, 25 of smallpox and 825 of typhoid fever. During the same period there were in Ohio 12 cases of meningitis, 153 of poliomyelitis, 38 of smallpox and 655 of typhoid. In South Carolina there were 143 cases of malaria, 33 of pellagra, and 134 of typhoid. There were 49 cases of poliomyelitis and 28 of smallpox in Minnesota and 167 cases of typhoid in Michigan.

POST-GRADUATE MEDICAL TEACHING IN PHILADELPHIA.—It is announced in the issue of *Science* for November 5 that over one hundred physicians of Philadelphia have joined in the formation of a coöperative association for post-graduate teaching of medicine in that city. The president of this organization is Dr. David Reisman, and the secretary Dr. George P. Müller. It is planned to establish a central bureau with a permanent secretary where the clinical and didactic opportunities of the city will be tabulated and correlated for the benefit of visiting students and graduates.

CONFERENCE OF TUBERCULOSIS WORKERS OF NORTH ATLANTIC STATES.—The opening session of the second annual conference of tuberculosis workers of the North Atlantic States held at Albany, N. Y., was given to the discussion of the subject "Tuberculosis and Industry." Addresses were made by members of the New York City Health Department, the American Association for Labor Legislation and statisticians of various large life insurance companies.

THE HOSPITAL SHIP "ANDROSCOGGIN."—In several issues of the JOURNAL last winter we commented editorially on the service of the revenue cutter *Androscoggin*, which was equipped as a hospital ship for fishermen and cruised for several months about the fishing banks and off the coast of Newfoundland and Nova Scotia. The value and importance of the service done by this ship in the prompt care and relief of sickness and injuries among fishermen has fortunately led to the intention of equipping her again for similar service during the coming winter. The hospital facilities aboard the *Androscoggin* have been enlarged and otherwise improved and on November 6 she sailed again from Gloucester for her initial cruise of the season. She will be at sea except when calling at Halifax for coal and water or to land patients for care in hospitals ashore. The ship is in command of Captain Van Boskerck.

DURATION OF IMMUNITY FROM SMALL-POX BY VACCINATION.—In a recent issue of the *Weekly Bulletin* of the Health Department of New York City, Dr. W. H. Park reports the results of investigations regarding the length of time of small-pox immunity conferred by a successful vaccination. He states that there are two means of judging this: the first is thorough observation of those who, having had a successful vaccination, are later exposed to small-pox, and the second, the duration of immunity to vaccination with vaccine virus. From statistics carefully compiled by the United States Public Health Service for a period of three years the following figures are obtained. Of 18,953 cases of smallpox, 798 had been vaccinated within

seven years preceding attack, 1,632 were vaccinated more than seven years preceding attack and 16,523 were never successfully vaccinated. It is calculated that 99.9% of persons who have never been vaccinated will "take" if vaccine is of high potency. As to the duration of immunity judged by revaccination, Lesechier finds that after one year 28% of persons become susceptible; after five years 50% become susceptible and 85% after ten years. Occasionally persons are met who can be successfully vaccinated at the end of six months. Dr. Park, therefore, draws his deductions that it is wise for anyone exposed to small-pox to be vaccinated, if a successful vaccination has not been obtained within nine months, and that the general population should be vaccinated about every five years when small-pox is at all prevalent. Even when the disease is absent all persons should be vaccinated in infancy and again in childhood so as to keep the population moderately immune and so prevent a sudden development of an epidemic.

EUROPEAN WAR NOTES.

EQUIPMENT OF FRENCH HOSPITAL TRAINS.—Report from Paris on November 1 states that a number of Americans, resident in that city, have interested themselves in the reorganization of the French hospital service, particularly the re-equipment of hospital trains for transporting the wounded from the front.

"The first step in improving the service was the addition to every train of a car equipped with an operating table and surgical supplies, so that wounded soldiers might be treated during the journey from the front to the permanent hospital, perhaps hundreds of miles away.

"One of the first cars so attached to a train was a freight car rebuilt at the expense of Mrs. Washington Lopp. She contributed the money to Commandant F. Loiseleur, in charge of the temporary hospitals at each of the railway stations of Paris, and of the construction yards of the state railway, and then requested other of her friends to provide money for the same purpose.

"To date a number of Americans have helped, one car having been fitted up by money sent from Hawaii, through Dr. James R. Judd and friends. Among other Americans thus contributing are Walter B. Hardy of Chicago and Mrs. Emory R. Johnson of Philadelphia. As a result of the rebuilding of these first freight cars for this purpose, to date not less than 50 cars have been remodeled with money contributed by individuals of cities of France. So great has been the use of these cars to the military surgeons that the War Department has authorized the placing of one with each of the 250 hospital trains now in service in France.

"Stimulated by the example of these Americans, Madame Marguerite Carre, the wife of the director of the *Comédie Française*, has just

equipped an entire train of 14 cars with money she collected. This magnificent train, known as the Carre train No. 15, is believed here to be the model hospital train of the world. The train has just made its first trip to the front, in charge of Dr. T. Tizon, who has been in service more than a year. He has stated that 300 wounded carried in the train were transported under admirable conditions, and without the loss of a single life.

"Service as physicians and nurses in these trains promises to become as popular among helping foreigners as that in the hospitals and ambulance corps.

"The friends of France among the allied and neutral nations now serving in the hospitals and ambulance corps number no less than 7000, of whom 2000 are Americans."

INFANT MORTALITY IN IRELAND.—The losses of life occasioned by the war seem already to have aroused the apprehension of publicists in the European countries on account of the inevitable decline in population which will ensue. In Ireland this apprehension seems to have given impetus to the attempt to reduce infant mortality in the hope of thus combating the depopulating effect of the war. This action is illustrated by the following extracts from the circular issued by the Women's Health Association of Ireland and widely distributed in that country.

"The ravages of war are rapidly thinning out the best young manhood of our nation. Tens of thousands in the prime of their days have gone forth to return no more. How are their places to be filled in the rising generation?

"It can be done by reducing the high rate of infant mortality in the towns of Ireland, and by preventing preventable illness amongst the growing children.

"But the war has already rendered this task doubly difficult. This is how it stands:

"Infant mortality, always far too high even in normal times, has increased since the war started. In Dublin it rose during the first quarter of the present year from an average of 145 to 181 per thousand. And this is not to be wondered at, for every bullet that kills a soldier wrecks two lives—his own and the life of the woman who loves him. And if that woman is the mother of his infant child its life too may be claimed by the same shot.

"Thus war, which claims the life of the soldier, by the privations, anxieties and sorrows which it brings upon his wife, often unfits her for the function of healthy motherhood, and the infant or unborn child is another victim in the national sacrifice.

"The Rt. Hon. Herbert Samuel, late president of the local government board, in a recent speech, estimated that in many districts a third of our possible population never survive their first year. To remedy this to some extent the government has decided to provide a grant for paying half the expense of duly approved organizations, such

as schools for mothers, infant welfare centres, infant clinics, etc. This is all aimed at training the mothers to save their little ones from death or a maimed life, to which ignorance on the mother's part so often dooms them.

"This is all the more necessary in Ireland where there is no medical school inspection, and no school medical officers to watch over the health of the children, and where the school buildings are often overcrowded and insanitary.

"It is, therefore, all the more necessary to watch over the health of the children in their infant years.

"In Dublin the average death-rate among infants under 1 year per every 1000 births for the last five years stands at 146, in Belfast 144, in Waterford 140, in Cork 121, and in 27 other towns in Ireland 132."

AMERICAN WOMEN'S WAR HOSPITAL.—It is announced that the makeup of the completed staff of the American Women's War Hospital, Oldway House, Paignton, South Devon, England, is as follows: Dr. D. Pearce Penhallow, chief surgeon; Dr. Fred C. Collier, assistant chief surgeon; Dr. James E. Daniel, Dr. Harold M. Frost, Dr. Russell P. Borden and Dr. Harold M. Goodwin, assistant surgeons; Dr. Arthur Casselman of the University of Pennsylvania, internist and bacteriologist.

INJURY TO KING GEORGE.—An item in a recent issue of the *Lancet* makes the following official statement about the recent accident to King George by a fall from his horse in France, which is evidently more serious than reported in the papers, since the King has been confined to bed for some days. The *Lancet* states, "There is no evidence whatever of any visceral lesion, or any fracture. Although the King is still confined to his bed, this is necessitated solely by a muscular stiffness."

THIRD HARVARD SURGICAL UNIT.—The third Harvard surgical unit, whose organization has been noted in recent issues of the *JOURNAL*, sailed from New York aboard the steamship *Noordam* on Wednesday of this week, Nov. 17. Its ultimate destination is not announced, but it will be landed first at Falmouth, England. Among the surgeons who have volunteered for service with this unit is Dr. Sir Wilfred T. Grenfell of Labrador. The unit will be in charge of Dr. David Cheever of Boston. The personnel of the unit consists of thirty-six nurses and the following physicians in addition to Dr. Cheever and Dr. Grenfell: Dr. John L. Bremer of Boston, Dr. Bronson Crothers of Cambridge, Mass., Dr. Abram L. Van Meter, Dr. John F. Dillon, Dr. H. R. McNair, Dr. Frank A. Smith, Dr. R. S. Catheron, Dr. A. A. Halliday, Dr. E. B. Towne, Dr. W. D. Jack, Dr. George Benet, Dr. E. W. Fiske, Dr. F. B. Abbott, Dr. L. R. Hill, Dr. W. O. Wilder, Dr. A. Gale Straw, Dr. E. O. Thomas, Dr. John C. Phillips, Dr. George Os-

good, Dr. George M. Watson of Manchester, N. H., and Dr. Macy Brooks of Philadelphia.

CHOLERA IN GERMANY.—During the week ended October 2 there was in Germany only one fatal case of Asiatic cholera which occurred at Kiel. There has been no genuine epidemic of this disease in Germany since the outbreak of the war and it appears that for the present season the sporadic incidence of the disease is probably at an end.

WAR RELIEF FUNDS.—On Nov. 13 the totals of the principal New England relief funds for the European War reached the following amounts:

Belgian Fund	\$277,704.36
American Ambulance Fund	63,292.00
Serbian Fund	37,280.05
Allied Fund	25,120.37
French Fund	23,153.56
St. George's Fund	12,085.54
LaFayette Fund	11,749.99
Armenian Fund	8,981.45
Surgical Dressing Fund	7,889.00

NEW ENGLAND NOTES.

SYPHILIS AS A PUBLIC HEALTH PROBLEM.—In the September number of the Public Health Bulletin issued by the State Department of Health, Dr. A. J. McLaughlin takes up the matter of syphilis as a public health problem. He states that he regards it as one of the most pressing public health problems of the time. He gives as reasons why it has not been treated as such the following:

1. There are no reliable statistics of the prevalence of the disease.
2. It is looked upon as a social disgrace to contract syphilis, and desire for concealment often causes the patient to neglect proper treatment or to fall into the hands of quacks and charlatans.
3. Among the poor and those in moderate circumstances the cost of salvarsan is often prohibitive.

Therefore, he believes that the State Department of Health should work toward the control of the disease in the following manner.

1. The disease should be reportable in a modified way.
2. Wassermann tests should be made free of charge by the State upon requests of physicians.
3. Salvarsan should be furnished free by the State to physicians for cases reported by number which have been found positive in the State Wassermann Laboratory.

The request of sanitarians to have cases of syphilis reported is not prompted by a desire to exercise quarantine powers over the individual but rather to secure statistical information which will aid in combating the disease. It is, therefore, unnecessary to give the name and address

but the reporting physician can report by number, giving all other interesting data.

This number can then be replaced by a serial number given by the State Department of Health and the physician then requested to make further reports or references under the serial number.

The Wassermann Laboratory of the State Department of Health began its work on June 1, 1915, and is now examining over 1000 specimens each month.

PREVALENCE OF DIPHTHERIA IN MASSACHUSETTS.—During the past month of October there has been in Massachusetts, a slightly increased prevalence of diphtheria over that of the corresponding month last year. It appears that the disease generally has its maximum incidence during this month. In October, 1914, there were 1,148 cases of diphtheria, with 77 deaths and in October, 1915, there were 1,175 cases with 44 deaths. In September, 1915, there were in Massachusetts only 598 cases of the disease. During this month 638 examinations of cultures were made at the State Laboratory and in October over 2,300 cultures were examined. The cities and towns in which diphtheria has been most prevalent during the past month are Agawam, Amherst, Attleboro, Brockton, Fitchburg, Haverhill, Hudson, Lawrence, Leominster, Lowell, Lynn, Malden, New Bedford, Revere, Rockport, Saugus, Shirley and Waltham.

MENTAL HYGIENE CONFERENCE AND EXHIBIT.—The mental hygiene conference and exhibit which was announced in last week's issue of the JOURNAL, is at present in progress in this city under the auspices of the Massachusetts Society for Mental Hygiene. The exhibit in Kingsley Hall, Ford Building, is one of the most elaborate ever shown on this subject. In a series of sixty charts is represented the ratio of mental disease in Massachusetts and in the United States, the causes of mental disease and the means of its prevention. A special group of charts demonstrates the social service and out-patient work done for psychopathic and nervous patients in the various state hospitals. There is an industrial display from fifteen of these hospitals exhibiting weaving, rug making, brass and clay work and other forms of occupation employed in the treatment of mental and nervous cases.

DETENTION OF A LEPER IN BOSTON.—A case of leprosy has been discovered in Boston and reported to the Department of Health. The patient, a Greek, was employed in a small restaurant in the West End and had been going regularly to one of the public hospitals for treatment. When the nature of his disease was definitely determined, the health authorities were notified and the man sent to the Southampton Street Detention Hospital, later to be sent to the leper colony on Penikese Island. He came to

this country from Greece three and a half years ago and has been in this city ever since. The other employees of the restaurant and the occupants of the house where the patient lived are under observation by the health department.

RESIGNATION OF DIRECTOR OF MILK AND BABY HYGIENE ASSOCIATION.—George R. Bedinger, director of the Milk and Baby Hygiene Association, has resigned from that position to become executive head of the Children's Aid Society of Detroit.

APPOINTMENT OF SCHOOL PHYSICIAN.—It is announced that Dr. Mary T. V. Moore, physician in charge of the baby clinic at the Massachusetts Homeopathic Hospital, has been certified by the Civil Service Commission and received her appointment by the Boston School Board as physician under its new organization.

Obituary.

GRACE WOLCOTT, M.D.

DR. GRACE WOLCOTT of Boston died suddenly on Nov. 9, at Heath, Massachusetts. Dr. Wolcott was the daughter of the late John Wesley and Henrietta Louisa Tracy (Eustis) Wolcott, and was born in Roxbury Feb. 15, 1858. She studied medicine at the Women's Medical College of Pennsylvania, from which she was graduated in 1884, later taking a post-graduate course at the Philadelphia Polyclinic and subsequently going to Vienna and Paris for more extended study. Dr. Wolcott had been a practising physician in Boston since 1884. She was a member of the American Medical Association, the Massachusetts Medical Society and the Boston Medical Library.

Dr. Wolcott's greatest contribution to women's work in medicine was her share in establishing Trinity Dispensary and the Vincent Memorial Hospital. Trinity Dispensary was the first dispensary to be established to be open evenings, and this offered an opportunity for working women to get medical advice without losing time and wages. Later to give further care to the same people, she helped to establish the Vincent Memorial Hospital. To both of these institutions she gave most devoted and wise service for about twenty years. For all who assisted or followed her, her standards of work were most stimulating.

In 1912, when Dr. Wolcott retired from active medical work at the hospital, she was made consulting physician and a member of the board of managers. At her camp in Heath, where she long had had patients, she was one of the first to try the system of providing occupation for nervous patients, a plan which is now in general use. She was a member of Trinity Church and was deeply interested in all its activities.

Dr. Wolcott's profession and her religion dominated her interests and her relationships. She was pre-eminently a physician alike of bodies and of souls. Radiantly alive herself, she rejoiced in all forms of life; and her keenest pleasure lay in spending herself that she might give fostering care to all living things from the blade of grass through all nature up to humanity. Strength mated with tenderness, faith and joy, boundless courage, unstinting devotion, marked her glowing personality, filling her with the life abundant, and so making her communicative of it to all who came under her care and influence. She had not been well for some time and had decided to spend the winter at Heath. There her earthly life came to an end; and with a swiftness and directness characteristic of all she did, she passed into eternal peace.

Miscellany.

INCREASE IN COST OF DRUGS.

THE continued increase in cost of drugs has progressed steadily since the latest note on the subject in the JOURNAL of November 4. Report from New York on Nov. 5 states that the cost of quinine, potash preparations and all narcotic drugs has advanced even more rapidly than that of other pharmaceutical and chemical products.

"Quinine scored its most sensational advance on the present upward movement this week when prices rose to \$2.50 and \$2.75 an ounce from a basis of \$2.15 an ounce. The advance from the normal basis of 26 cents an ounce will probably go further as cable advices received from London state that the British Government has just placed quinine sulphate on its list of prohibited exports in order to prevent depletion of its own supplies. This vital development in the quinine situation leaves the United States dependent upon its own domestic production, which amounts to only 1,500,000 ounces of quinine annually, or only one-half as much foreign sulphate as is imported into the United States annually during normal times, that amount being 3,000,000 ounces.

"The heavy consumption of quinine for the war has, of course, been the principal factor in the rise in the article. All of the European belligerents have been in the domestic markets for amounts beyond credence. It is said on reliable authority that more than 500,000 ounces of domestic and foreign quinine sulphate have been exported since the commencement of the European War, but verification of these figures is impossible, as exporters have in many instances refused to declare the identity of the commodity offered for export or have resorted to the subterfuge of concealing the name of the drug under a proprietary name.

"The conditions which brought about an advance in quinine prices to \$5 and \$6.50 an ounce during the Civil War bid fair to be duplicated here within the next few weeks. The American salts makers are utilizing all their stocks and current output in filling outstanding contracts and have been forced to decline to book any new business. The local market continues bare of Java and Amsterdam salts at any figure, and German salts have long been unobtainable in this market.

"In order to gain an idea of the present position of the article it is well to remember that cinchona bark, the basic material, has advanced from 15 to 25 cents a pound. It is understood that the allotments of bark to domestic manufacturers by Java bark growers have been very small. Import figures for the first eight months of the current year to the end of August indicate a falling off to only 2,736,690 pounds of bark as against 3,230,985 pounds in the corresponding ten months in 1914, and 3,944,509 for the calendar year ended December, 1914. The material diminution in the shipments of cinchona bark from Java, together with the cutting off of the output of the large German factories which formerly produced 7,000,000 ounces of quinine annually, may again lead to the usage of the native South American Peruvian bark which is found in a belt 100 miles wide by 2000 miles long, extending through Venezuela, New Granada, Ecuador, Peru, and Bolivia.

"All the various manufacturers of mercurial preparations have been forced to advance prices eight cents a pound on the 'hard' and three cents a pound on the 'soft' in consequence of the high cost of quicksilver. This is the third advance announced in mercury preparations since June 28 last and prices in fifty-pound lots in one delivery for hard mercurials are now given by the manufacturers; as calomel, \$1.51 a pound; corrosive sublimate, powdered, \$1.38 crystals, \$1.43; mercury bisulphate, \$1.29; red precipitate, ordinary and powdered, \$1.64 and \$1.74, respectively; white precipitates, ordinary and powdered, \$1.74 and \$1.79 respectively. The soft mercurials are now quoted in fifty-pound lots in one delivery at: blue mass, 75 to 77 cents mercury and chalk, 77 cents; mercurial ointment (one-half mercury), 93 cents a pound citrine ointment, 75 cents a pound.

"An unprecedented upheaval of drug and chemical market conditions has taken place in nearly all other products and has carried prices with few exceptions to the highest point in history. Practically every drug and chemical product known to modern science has at least doubled in price since the commencement of hostilities in Europe, and some products have risen as much as 3000%. In cases where the import movement of drugs and chemicals from Europe, Russia in Asia, Turkey, Egypt, Japan or China has not been entirely suspended, the amounts of such commodities being released by the factors

at the seats of production are so small as to be considered of negligible importance.

"American manufacturers of finished and semi-finished drug products have been forced to advance quotations on every conceivable material in order to protect themselves against further advances in costs of crude materials caused by scarcity and high prices of labor abroad. This has brought about an upheaval in conditions such as has never before been witnessed, and in many instances makers have entirely withdrawn their offerings in order to prevent supplies from reaching the hands of speculators. The latter interests have been and are still reaping a harvest of dollars, in their capacity as middlemen for purchasing agents of the Allied Governments.

"A sensational advance has taken place in all narcotic drugs, following the realization on the part of all domestic handlers that the unabated bombardment of Constantinople by the Allied fleet, as well as the cutting of the Nish-Salonica railway by the Teuton Allies renders present opium stocks impossible of replacement. Drug-gist's quality gum opium has been advanced 25% within the past few days and now commands \$10.25 per pound, while powdered opium is selling at \$11.25 and \$11.50 and granular at \$11.50 and \$11.75 per pound. While import statistics would indicate little concern over the position of opium, imports for eight months ended in August last having totalled 298,270 pounds of the value of \$1,456,816 against 258,704 pounds of the value of \$1,141,132 in the same time in 1914, there has been a steady diminution in the supplies in United States bonded warehouses, as well as in the hands of dealers, owing to the export demand, both for opium derivatives and for the gum itself. The stock of opium containing 9% or over of morphia in United States bonded warehouses on July 1, last, stood at 92,997 pounds of the value of \$394,088. The stocks of opium in bonded warehouses on Sept. 1 had declined to 67,687 pounds of the value of \$293,658, a decline of \$100,430 in value. A corresponding shrinkage was noted in the stocks in dealers' hands.

"In view of the greatly increased cost of opium, domestic manufacturers of all of the derivatives therefrom have been forced arbitrarily to advance their prices in order that they might bear their approximate proportion of cost of the newly established value of sulphate of morphine and codeine. Thus quotations for morphine sulphate have been advanced 50 cents an ounce to a basis of \$5.50 an ounce for 5-ounce cans, \$5.55 an ounce for 1-ounce cans, \$5.75 an ounce for 1/8-ounce vials in 2 1/2-ounce boxes, and \$5.80 an ounce for 1/8-ounce vials in 1-ounce boxes; while morphine acetate and morphine alkaloid in 1/8-ounce vials have been advanced to a basis of \$7.15 an ounce in 25-ounce lots. Codeine sulphate also has advanced to the extent of 50 cents an ounce, and \$6.95 is now asked for sulphate and hydrobromide of codeine

in 1/8-ounce vials. The new schedule on codeine alkaloid and other salts is much higher than that on the sulphate, sellers naming \$8.60 for alkaloid, \$7.80 for acetate, chloride and nitrate, and \$6.55 an ounce for phosphate and salicylate. Other morphine derivatives in 10-ounce lots are advanced to \$6.70 for diacetylmorphine hydrochloride, \$7.35 for diacetylmorphine alkaloid, \$7.90 for ethylmorphine hydrochloride, and \$16.80 for apomorphine hydrochloride. No contracts or orders calling for forward deliveries are today being entered by manufacturers at these figures, but the makers are busy accepting orders for prompt deliveries at these quotations."

Correspondence.

A STUDENT'S POINT OF VIEW.

Boston, November 5, 1915.

Mr. Editor: It has been my observation in the various hospitals in which I have worked as a student, that many medical men appear to look on surgeons as knaves who will operate on anyone on whom they can lay their hands, and that they, therefore, hesitate greatly in sending patients to them. Some surgeons, on the other hand, seem to regard medical men as fools, and, feeling that they are themselves competent to treat any medical case, will not transfer cases for treatment to their colleagues. The result is that there are patients in our hospitals who suffer because of the lack of an all-round view on the part of men having their care. One cannot help feeling that, had the physicians and surgeons taken hospital appointments which included some medicine and some surgery, each would have been more lenient to the other.

Furthermore, despite the fact that "the day of the general practitioner is over," a canvass of three recently graduated classes of the Harvard Medical School shows the following figures:

Total number heard from.....		86
<i>Hospital Appointments.</i>		<i>Additional Hosp. Appointments.</i>
Medical 27	Children's obstetrical and contagious	1
	Obstetrical	3
	Gynecological and obstetrical.....	1
Surgical 26	Children's	1
	Mixed	1
Mixed 27	Surgical	1
	Children's	1
	Children's and obstetrical.....	1
Path.	1	
None	5	
Doing a general practice.....		46
"Work largely surgical".....		1
"Institutional work including both medicine and surgery"		1
"Medicine and surgery"		1
"Some minor conditions any M.D. can treat (not really surgical) come into my practice"		1
		50
Doing medicine now		18
(One on a "mixed" training)		
Doing surgery now		8
(One on a "mixed" training)		

doing medicine and obstetrics.....	1
doing surgery and obstetrics.....	2
doing eye, ear, nose, and throat	1
doing laboratory work	5
Not practicing	—
	33

Of the 50 men who are, to all intents and purposes, doing a general practice.

26 took mixed appointments.	<i>Additional Appointments.</i>
15 took surgical appointments.	Obstetrical 1
	Mixed 1
7 took medical appointments.	Children's, obstet.,
	plus contagions.. 1
1 took surgical plus medical.	
1 took no appointment.	

From these results it may be seen that approximately 58% of the *recent* graduates are doing a general practice, and that about 40% of these are doing so on an inadequate training. The reason for this unfortunate state of affairs seems to be that most men want to take their hospital training in the teaching centres, where it is to be presumed that the best teachers are to be found, and that this particular centre (into which most Harvard graduates naturally drift) has abolished the mixed service from its larger hospitals. Few men care to begin at the foot of a service after they have already reached the position of senior on a parallel service, or to repeat the routine laboratory work. And whatever the condition of affairs in the future may be, at present the public suffers.

It is not my plea that the training now given in these large hospitals in either medicine or surgery be cut down, but that in addition to the time now given to either, a training in the other branch also be offered. Thus a man taking a twenty-two-month medical appointment would have the opportunity of doing eleven months of surgery, and *vice versa*.

P. R. W.

UNITED STATES CIVIL-SERVICE EXAMINATION

ASSISTANT IN METABOLISM INVESTIGATIONS
(MALE), \$1500.

December 8, 1915.

The United States Civil Service Commission announces an open competitive examination for assistant in metabolism investigations, for men only, on December 8, 1915. From the register of eligibles resulting from this examination certification will be made to fill vacancies in this position in the United States Public Health Service for duty in the field at a salary of \$1500 a year, and vacancies as they may occur in positions requiring similar qualifications, unless it is found to be in the interest of the service to fill any vacancy by reinstatement, transfer, or promotion.

The duties of this position will be to make complete food analyses, including calorimetric determinations. Appointees will also be required to use the respiration apparatus for the determination of the energy metabolism.

Graduation from a four-years' course at a college, university, or medical school of recognized standing and at least six months' practical experience in work with the respiration apparatus and the calorimeter are prerequisites for consideration for this position.

Applicants must submit to the examiner on the day of the examination their photographs, taken within two years, securely pasted in the space provided on

the admission cards sent them after their applications are filed. Tintypes or proofs will not be accepted.

This examination is open to all men who are citizens of the United States and who meet the requirements. Persons who meet the requirements and desire this examination should at once apply for Form 1312, stating the title of the examination for which the form is desired, to the United States Civil Service Commission, Washington, D. C. Applications should be properly executed, excluding the medical and county officer's certificates, and filed with the Commission at Washington in time to arrange for the examination at the place selected by the applicant. The exact title of the examination as given at the head of this announcement should be stated in the application form.

AUTHORS' EVENING.

The Fourth "Author's Evening" of Ten Papers, "A Second Contribution to the Neurology of Childhood," by Walter B. Swift, M.D., and assistants: C. A. Osborne, M.D., Ph.D., second assistant; Miss Jennie Hedrick, voluntary assistant. AT THE VOICE CLINIC, PSYCHOPATHIC HOSPITAL, 74 FENWOOD ROAD, NOVEMBER 19, 1915, AT 8 P.M. 1. The Signs and Symptoms of Stuttering. 2. The Physical and Mental Examination of Stutterers. 3. The Thymus as the Seat of Stuttering—Browning. 4. Relation of Stammering to Right and Left-handedness. 5. Medical Aspects of Stuttering from the Teacher's Standpoint. 6. Incongruities in the Freudian Concept of Stuttering. 7. Five-Minute Summary of Spirometer Findings in Stutterers. 8. Further Psychological Steps in the Recovery of the Same Stutterer. 9. Psycho-physiological Analysis of Stuttering. 10. Locating the Speech Center by Hand Motions in Stutterers. First Note.

Physicians and medical students are invited.

Kindly drop a postal, if you expect to attend, to 110 Bay State Road, Boston, Mass.

APPOINTMENTS.

UNITED STATES PUBLIC HEALTH SERVICE.—*Dr. W. McCoy*, recently in charge of the investigations at the leper hospital in Molokai, Hawaii, has been appointed director of the Hygienic Laboratory of the United States Public Health Service to succeed *Dr. John F. Anderson*, who has resigned.

UNIVERSITY OF CINCINNATI.—*Dr. Robert S. Morris* has been appointed Frederick Forchheimer professor of medicine.

UNIVERSITY OF CONSTANTINOPLE.—*Dr. Boris Zarnik* of Würzburg, Germany, has been appointed professor of zoology.

UNIVERSITY OF HONG KONG.—*Dr. H. G. Earle* has been appointed professor of physiology.

UNIVERSITY OF NEVADA.—*Dr. Robert H. Mullin*, formerly director of laboratories of the Minnesota State Board of Health and assistant professor of pathology and bacteriology at the University of Minnesota, has been appointed to take charge of the hygienic laboratories of the University of Nevada at Reno.

UNIVERSITY OF UTRECHT.—*Dr. Hermann Jordan* of Tübingen, Germany, has been appointed associate professor of comparative physiology.

RECENT DEATH.

DR. GRACE WOLCOTT, of Boston, died at Heath, Mass., November 9, aged 57 years. She was a councilor of The Massachusetts Medical Society from 1901 to 1913.

WHAT THE GENERAL PRACTITIONER SHOULD KNOW ABOUT INCIPIENT PULMONARY TUBERCULOSIS.*

By VINCENT Y. BOWDITCH, M.D., BOSTON.

WHEN one recalls the almost endless amount of literature that has been given out on the subject for discussion today, he feels a natural hesitation in adding anything to what has already been said and written upon what would seem to be self-evident, viz.: the importance of early diagnosis in pulmonary tuberculosis.

Notwithstanding the great strides that the anti-tuberculosis work has taken in the past few years, it is still necessary to keep constantly before the public certain important factors that are essential to success in our efforts to control the disease.

That there has been comparatively lately a most gratifying change of attitude among a large number of the medical profession on this point must be evident to all those who have made for years a special study of the disease. The number of physicians who now seek a specialist's advice in obscure cases has greatly increased, but there is still much to be learned among the rank and file of the profession as to what really constitutes an incipient case; and there is even now a lamentable lack of care in paying attention to obscure but definite symptoms, which, if

not promptly noted and measures taken to counteract them, will mean disaster to the patient.

The time has passed when, with symptoms of malaise, loss of flesh, and cough, no matter how slight, whether accompanied or not by feverish symptoms, the patient can be put off lightly with some hasty and often erroneous diagnosis. Too many patients, who, without proper examination, have been told they have a "stomach cough" or a "bronchitis," consult some one else, often the specialist, who finds definite evidence of tubercular disease. With our present knowledge, such superficial decisions are nothing short of culpable, and the harm done to the patient is often incalculable. It is, moreover, still a source of regret and surprise to many a specialist to note the number of patients who come to him with supposedly incipient disease which is really in a well-advanced stage, the extent of which has not been recognized by the attending physician until too late to accomplish anything other than a more or less temporary arrest of the disease, with little hope of permanent recovery.

I should be sorry if, by the foregoing remarks, I seem to disparage the frequently fine and noble work of the large army of general practitioners, especially those in country practice who have not the facilities for work that surround those who live in the city. My respect for the work and opinions of such medical men is of the very highest. All that I say is in criticism only of the methods of some (far too many) who do not pay sufficient attention to symptoms which may be indicative of beginning tuberculosis and therefore are really guilty of neglect of their patients.

* Read at the second annual New England Tuberculosis Conference under the auspices of the National Association for the Study and Prevention of Tuberculosis, at Westfield, Mass., Oct. 23, 1915.

It would, of course, be unjust in the highest degree to expect the general practitioner, no matter how conscientious and skilled in his profession, to be proficient in some of the finer methods of diagnosis which are possible to those who are making special studies of any one disease; and there can certainly be no loss of prestige or dignity to a physician if, in accepting this fact, he therefore calls to his aid expert advice in any doubtful case, and so gives his patient the best chance of regaining his health.

This brings us also to the undoubted fact of the lack of sufficient clinical instruction at present in most, if not all, our medical schools in methods of examination for tubercular disease in its pulmonary form. This is due, not to lack of ability in the teachers themselves, but to lack of time given to the subject and insufficient clinical instruction as to the various degrees or stages of this disease. I think it is not too sweeping an assertion to say that the ordinary medical student upon graduation can perhaps easily recognize a sonorous râle and the difference between absolute flatness in percussion and normal pulmonary resonance, but when launched upon the world, it is the exception when he is able to diagnose an incipient case of tuberculosis with its delicate shades of abnormal symptoms, although doubtless he can, with comparatively slight medical knowledge, usually recognize one that is in the later stages.

The argument that it takes a vast deal of time to become proficient on these points,—more than is possible in the ordinary curriculum of a medical school,—does not do away with the fact that most students are not sufficiently equipped in these matters, and that more can be done and should be done to remedy these deficiencies if we are to make proper progress in our anti-tuberculosis work. I regard it, therefore, as one of the essentials for success in the future that medical schools should be urged to greater activity in this direction.

What, then, constitutes an incipient case of pulmonary tuberculosis? It is not necessary here to launch upon a discussion as to whether or not all cases owe their origin to lesions formed in childhood and which remain dormant. Our chief concern now is to know how to detect at the earliest moment any possibly latent process which is bursting into sudden activity, no matter at what stage of life.

The National Association for the Study and Control of Tuberculosis, in conjunction with the American Sanatorium Association, published a short time ago a series of tables as a guide to classifying the various stages of the disease.* These tables have been prepared by committees of these associations after several years of frequent consultation with each other. I speak from long experience in knowing how difficult it is to get any set of classifications which shall

be satisfactory to everybody. Necessarily all such classifications are more or less arbitrary, and are open to certain objections and limitations, but as a rule these serve as a basis for comparison and answer the purpose fairly well.

What symptoms are important to put physicians on their guard lest disease is beginning? In general, one may say, if a patient presents himself with a history of malaise for a number of weeks, loss of appetite and flesh; and if there has been ever so slight a cough or "clearing of the throat," with or without expectoration; and if upon trial a slight rise of temperature and an accelerated pulse are found; make a thorough examination of the chest at once, or as soon as possible after the visit if unable to give the proper time at first.

If, upon examination of the chest, a difference is found in the percussion note at the apices other than what normally exists consistent with health in a great number of people, viz.: a heightened pitch in the right apex; if there be any special departure from normal in the character of the respiration at either apex or locally elsewhere, combined with the symptoms above mentioned, *watch the patient* and keep him under supervision, with occasional examinations to detect any possible development.

If, moreover, a "click," a wheezing sound, or a râle of any nature, is found in one or the other apex of the lungs, watch carefully; and if the signs persist, you may be moderately certain without further assurance that trouble is brewing. Modern research has taught us that possibly these apical conditions may be consistent with disease other than tuberculosis (grippe, for instance), but in thirty years of practice, I have never failed to heed the excellent advice that was given me over and over again by my best teacher:

"If, with a history of abnormal symptoms lasting for a longer or shorter space of time, upon examination you find anything out of the normal at one or the other apex, watch your patient closely, for the chances are that there is or has been tubercular trouble there."

I am not referring now, of course, to the cases of apical pneumonia not uncommon in children but rare in adult life. There are always exceptions to every rule, but one cannot go very far wrong if, under such conditions as I have mentioned, special measures are taken to increase the patient's powers of resistance to the utmost and to keep him under supervision.

As aids to diagnosis, first, where possible, is the immediate examination of the sputum. *Do not delay.* There is no excuse for delay with our present state and municipal facilities for such examinations. If tubercle bacilli are found, of course we have the surest proof of the presence of tubercular disease, always remembering, however, that repeated *negative* examinations do not necessarily mean that no tuberculosis is present. In such cases, give the patient the

* Report of the Committee on Clinical Nomenclature. Transactions of the National Association for the Study and Prevention of Tuberculosis. Ninth Annual Meeting, 1913, p. 243.

benefit of the doubt, and do not relax in your observation of him.

As further aids to diagnosis, we have the oft-mentioned and frequently-used tests with tuberculin, either by the von Pirquet (skin) test, the ophthalmic test (now less frequently used), and the subcutaneous test, the most reliable of all. All are to be resorted to, however, only as corroborative of other positive symptoms; no one is to be relied upon solely, the von Pirquet test having proved to be of less value after adolescence than in the earliest years. In the subcutaneous test, the method which we have ordinarily made use of at the Sharon Sanatorium is, after making sure that the patient is free from heightened temperature for several days, to inject two milligrams of Koch's "old tuberculin," the patient being kept in bed and a four-hour chart taken to note any possible rise of temperature accompanied by symptoms of greater or less malaise during the ensuing 48 hours. Should two milligrams bring about no reaction, then five milligrams should be injected with the same procedure, a few days after the first dose; and finally a dose of ten milligrams, should the earlier trials be negative in result. One observer of high repute claims that if the smaller doses fail to give a reaction, it is not necessary to give the largest dose mentioned; but inasmuch as we have the authority of Koch himself, our usual custom seems justifiable, failure to react after the largest dose probably meaning that no tuberculosis is present.

The use of the x-ray has come to the fore in recent years and much is claimed for it as a valuable adjunct in the diagnosis of tuberculosis, whether doubtful or otherwise. By some,—I think I may say, a minority,—it is claimed that early doubtful cases can be more easily demonstrated as positive by the use of the x-ray than by auscultation and percussion. On this point, I must confess to considerable skepticism. One can easily conceive that an expert with the x-ray can see much that is not discerned by a less well-trained eye; but I find it thus far in my experience difficult not to believe that the examiner with a well-trained ear can more easily detect the slight abnormalities of incipient pulmonary disease, especially if the lesion be near the surface, than one who depends upon the presence of shadows made by the x-ray for his diagnosis. The comparative excursion of the two portions of the diaphragm as shown by the x-ray and demonstrated first by Dr. F. H. Williams, is a valuable adjunct in determining an abnormal condition of the lung.

In spite of the great advance that has been made in the practical use of the x-ray of late years, I can but feel that we have not yet sufficiently studied the causes of the phenomena shown by this method to warrant our drawing what have seemed to me at times hasty conclusions as to the amount and nature of disease which may be present in the lung. One thing is

absolutely certain in my mind, viz.: that I have very little faith in the findings of any one but those who are experts in this department of science, and I most unhesitatingly condemn the diagnoses of tyros who, upon the insufficient ground of their own supposed findings in the use of the x-ray, give their patients unnecessary alarm and anxiety as to their bodily condition.

In conversation with experts I have been impressed and pleased by the conservatism which they have expressed on these points, for in that very attitude they show their own breadth of mental vision. Many times I have been told by them that, although they have been able to detect certain abnormal shadows over portions of the lung, they are quite unwilling often to make any positive diagnosis of the cause, although admitting the possibility that tubercular processes may be, or have been, present, while diseases of less serious nature, like grippe or bronchitis, may have been the causes of abnormal thickening of the lung tissue.

That future developments may bring us even greater proof of the efficacy of x-ray examinations in suspected lung disease, I am quite ready to believe, and I should regret it if I seem to disparage the work done by specialists in this department. I wish only to utter a word of caution against hasty conclusions made through lack of experience. As an illustration of this, allow me to cite one concrete example which came under my observation a few years ago. A young woman presented herself for examination because of great perturbation of mind from having been told after an x-ray examination of her chest by beginners in that branch of work, that she had "shadows in the upper portions of her lungs," and that she "showed signs of tuberculosis." This diagnosis was based solely on the x-ray examination. She had consulted a physician because of an annoying and persistent pain under the left scapula for a few months. This had been the cause of sleeplessness and much fatigue. She had had no symptom otherwise to make one suspect tuberculosis. She had been in perfect health in previous years; no trace of cough, expectoration, fever, loss of flesh, or other abnormal sign; but her mental condition consequent upon the grave diagnosis given her was distressing. A full examination of the chest by auscultation and percussion failed to reveal the slightest trace of pulmonary disease, and I felt convinced the pain was due to some pressure on an intercostal nerve, due partly to her occupation. I sent her to an orthopedist, who promptly made the same diagnosis, supplied a certain kind of corset, and in two weeks the absolute relief to the patient, both physical and mental, was something never to forget. The pain entirely disappeared and the patient has been perfectly well, and she wrote later of her excellent health and entire freedom from abnormal symptoms. A case of this sort should teach us much as to the unwisdom, to say the least, of hasty diagnoses.

Far more important, to my mind, than the results of tuberculin tests or x-ray examinations, is the patient's history, past and present, which usually throws a vivid light upon the whole question; his general condition, and his appearance, combined with the signs found upon the examination of the chest by auscultation, percussion, palpation, etc. If, added to those data, we have the aids to diagnosis just mentioned, we can with increased confidence advise as to what course should be taken by the patient to regain his health.

As a summary, therefore, of all that has just been said: The vital point in all examinations of patients is that we must not depend upon any one method alone unless the disease is so apparent that a mere tyro could make a diagnosis. That cases often appear which tax the skill and knowledge of the most expert observers, and in which it may at first be impossible for any one to make an absolute diagnosis, would seem to be a self-evident truth.

In thus speaking of the methods which should aid us in making the diagnosis of incipient pulmonary tuberculosis, I have touched only upon those which are most commonly used; and I have purposely refrained in this paper from alluding to some which are mentioned by various authors who lay stress upon certain methods which do not seem thus far to be of sufficient scientific or diagnostic value for ordinary use. They come more into the realm of the specialist, who has the opportunity usually for making more extensive observations than the general practitioner, and are interesting rather than of marked use in making a diagnosis. Among these, perhaps that mentioned by some writers as the "sign of D'Espine" is one of the most familiar, in which a certain bronchial character to the whispered voice in areas between the spine and the scapulae has seemed to indicate the presence of enlarged tubercular bronchial glands in children. It is extremely doubtful, however, I think I may say to most observers, whether this sign is absolutely to be relied upon as a means of definite diagnosis, although some writers believe that it has great value in this special form of disease, while granting that it may be not infrequently due to causes other than tuberculosis.

We have a long and difficult path ahead of us still in our endeavor to bring tuberculosis into the ranks of the diseases that can be kept under control; but with the great advance already made, there is hope ahead of us and no reason for discouragement, even if at times the goal seems far distant. It is only by constant reiteration of what would seem to be often self-evident truths, that we make headway. I trust that in placing before you certain opinions formed by my own experience, I may be adding something, however little, towards the desired result.

Discussion.

I.

THE MEDICAL ASPECTS OF EMPYEMA AND PULMONARY ABSCESS.*

BY FREDERICK T. LORD, M.D., BOSTON.

A CONSIDERATION of the medical aspects of empyema and pulmonary abscess has been assigned to me, and in the limited time at my disposal it seems best to speak briefly of empyema and more fully of abscess†. So far as empyema is concerned I shall attempt to consider only certain aspects of the treatment.

EMPYEMA.

Whether the treatment of pleurisy with effusion should be medical or surgical depends for the most part on the character of the fluid, concerning which it is desirable to know the gross appearance, whether clear, cloudy, or opaque, the specific gravity, the amount of albumen contained, the character of the cells obtained after sedimentation, the results of cultural tests for bacteria, and in certain instances the results of animal inoculation. Excluding from discussion other than the inflammatory fluids, an important matter to decide is whether the treatment is to be by thoracentesis or by operation.

It is generally agreed that clear serofibrinous effusions should be evacuated when there are pressure symptoms or when the fluid is of large amount, and that effusion of medium amount should be removed when, after the ineffectual trial of other methods, two or three weeks have elapsed. In such cases thoracentesis is the procedure of choice.

* Presented before The Massachusetts Medical Society, June 9, 1915.

† Empyema and pulmonary abscess have been discussed by me elsewhere as follows: The "Diagnosis and Treatment of Abscess and Gangrene of the Lungs, with Special Reference to Operation," *Internat. Clinics*, Vol. ii, 16th S., 1906. "Diseases of the Pleura," *Oster's Med. Med.*, 1907, Vol. iii. "Disease of the Bronchi, Lungs and Pleura." Lea and Febiger, Philadelphia, 1915.

The judgment is more difficult in those cases in which there is a turbid effusion or one on the border line between serofibrinous and purulent fluid. It is desirable to know the cause of the turbidity, which may be due to the presence of albumen in fine subdivision, fibrin in the form of flocculi, clot, fat or cellular elements. While the presence of blood or a large amount of pus may be sufficiently obvious on gross inspection, more careful study of the fluid is the part of wisdom if mistakes are to be avoided. The character of the cellular elements and the results of cultures are of most importance in deciding whether thoracentesis alone, or operation, is necessary. With turbid fluids, which contain merely an excess of polynuclear leucocytes, evacuation by thoracentesis may be sufficient to effect a cure, as in 15 of 27 cases at the Massachusetts General Hospital. In the remaining 12 cases pus was demonstrated at later tapping and thoracotomy was performed. Turbid fluids containing merely an excess of polynuclear leucocytes secondary to lobar pneumonia or due to the pneumococcus are relatively favorable for thoracentesis. Pneumococci may be demonstrable in stained smears from such material, but may be incapable of cultivation. Even with positive cultures for pneumococci, frank empyema does not necessarily follow, and thoracentesis alone may be tried. With turbid fluids containing abundant or necrotic leucocytes and positive cultures for pneumococci, operation is usually necessary. Streptococcus infections rapidly tend to become purulent and generally demand operation. In the decision between thoracentesis alone and open incision, such other factors as the degree of sepsis, the amount of fluid and the rapidity of reaccumulation must also be considered.

With frankly purulent effusions, on the other hand, except as noted below, an immediate and free drainage of the pleural cavity is essential for prompt and permanent cure.

It is important to remember that an open incision is not the procedure of choice in all empyemata. In those cases in which the pus is sterile on cultivation or contains tubercle bacilli alone it is best to evacuate the fluid by thoracentesis. Open incision is likely to be followed by a persistent sinus. Tuberculous empyema complicated by infection with pyogenic cocci is usually best treated by open incision, when the effusion occurs early in the course of pulmonary tuberculosis, but in the advanced stages of the disease a radical operation can hardly be considered, and repeated puncture may be tried.

In the presence of large collections of pus in the pleural cavity in patients who are gravely ill, evacuation by thoracentesis may well be undertaken as a preliminary to operation or as a life-saving measure. In such patients the sudden change in the mechanical conditions after open incision is often followed by a rapidly fatal termination.

PULMONARY ABSCESS.

In considering this subject I shall not attempt to distinguish between abscess and gangrene, and propose to discuss the two processes together. Grouping together the cases I have collected from the records of the Massachusetts General Hospital and those seen in consultation, there are in all 185 cases.

Certain features in the etiology are worthy of note. In 55 cases the cause is not wholly clear, but from their insidious onset or occurrence following an acute infection of the upper parts of the respiratory tract an origin from bronchopneumonia may be suspected. Abscess is not an infrequent finding at autopsy in cases of broncho-pneumonia. Of 85 cases of bronchopneumonia coming to autopsy at the Massachusetts General Hospital abscesses were found either macro- or microscopically in 16, a proportion sufficiently high to suggest that, had these patients survived, the losses of pulmonary substance would probably have proceeded to full recovery in many instances.

The next most important cause is lobar pneumonia, which is represented by 30 cases. In lobar- as in broncho-pneumonia, the development of abscess is an infrequent clinical finding, but more common at autopsy. Thus of 51 cases of lobar pneumonia coming to autopsy abscesses were found either macro- or microscopically in 14, suggesting that the clinical infrequency of abscess in lobar pneumonia is more apparent than real, and that certain cases of pneumonia are complicated by small losses of pulmonary substance which proceed to full recovery.

Another important cause, represented by 25 cases, is the aspiration of infected material into the deeper parts of the respiratory tract. In this group are included such abscesses as arise after etherization for operation upon parts of the body remote from the respiratory tract (10 cases), the extraction of teeth (5 cases), the removal of tonsils (2 cases), and adenoids (1 case), the inhalation of foreign bodies (4 cases), and submersion (3 cases). The unfortunate occurrence of pulmonary abscess in this group is not always avoidable, but its incidence will diminish with greater caution in selecting the time for operation under ether, and the postponement when possible of operative interference, until the respiratory tract is clear of infection, greater care in the prevention of inhalation of blood or other material during operations about the mouth and the naso-pharynx and the early removal, with the aid of bronchoscopy, of inhaled foreign bodies.

Regarding the pathology of abscess, there are certain aspects of the process with a bearing on surgical intervention and consequently a special interest on this occasion. Pulmonary destructive lesions are more often multiple than single. They are usually situated toward the periphery of the lung near the pleura and not deep within

the substance of the lung. This prevailing subpleural site is worthy of the attention of the surgeon, who would do well carefully to explore the more superficial parts of his field of operation in difficult cases before proceeding to deepen his incision. All destructive pulmonary lesions are complicated after a time by the development of indurative pneumonia, which is more dense and more extensive the longer the disease has lasted. Induration of the tissue about the abscess diminishes the likelihood of successful operative interference. The pleural layers overlying the destructive pulmonary process are adherent or separated by purulent fluids in about one-half the cases. It must be appreciated that time is an important element in modifying the pathology of abscess, and that the longer the process has lasted the more likely are the lesions to be multiple and surrounded by indurated tissue.

The clinical manifestations are, in general, those of sepsis, with fever, elevated pulse, sweats, chills and leucocytosis, and with special reference to the lung, cough and the expectoration of purulent and oftentimes foul material. If the case is seen at a time when the abscess has not yet ruptured,—an uncommon occurrence,—there may be the clinical features of sepsis with trivial local symptoms. Sputum is usually present from the beginning and expectorated in smaller or larger amounts at frequent intervals, less commonly in large amounts at infrequent intervals. Hemoptysis is a feature in a small proportion of the cases.

The pulmonary signs are very varied. There may be only the persistence of râles at one place in the lung or typical signs of consolidation, *i.e.* dullness, bronchial breathing, increase of voice, whisper and tactile fremitus. The signs of cavity,—tympany on percussion, amphoric breathing, metallic râles, etc.—are demonstrable only in a small proportion of the cases, and their absence should not be regarded as evidence against the presence of pulmonary abscess.

There are three indications which I have come to regard as a most important triad of signs. The sign which is common to the largest number of cases is dullness on percussion, which may or may not be accompanied by other physical findings. It may be very marked or elicited only by careful comparison of the percussion note on the two sides of the chest. The second indication is the evidence of a circumscribed increase of density of the lung on x-ray examination, and this is almost indispensable when surgery is under consideration, since it is of material assistance in the exact localization of the process and the exclusion of numerous small multiple foci which might make operation inadvisable. The third important factor in deciding upon the presence of a destructive lesion is the demonstration of elastic tissue with an alveolar arrangement in the expectoration. If elastic tissue cannot be found there is the possibility of mistaking the disintegration of pus in a dilated

bronchus for a pulmonary abscess. It is highly desirable in making the diagnosis of abscess to have these three signs positive, but it is by no means necessary that they should all be present, and of the three I have failed most often to demonstrate elastic tissue.

It is of paramount importance before making the diagnosis of a non-tuberculous destructive process thoroughly to exclude tuberculosis, and the sputum should be carefully and repeatedly sought for tubercle bacilli. It is manifestly easier to exclude tuberculosis in these lesions than in cases suspected of incipient tuberculosis, because a pulmonary process which has progressed to the stage of tissue destruction without showing tubercle bacilli in the sputum is not likely to be tuberculous. The presence of elastic tissue and the absence of tubercle bacilli in the same specimens is a double assurance against the tuberculous nature of the destructive process.

One caution I should like to emphasize in attempting to make the diagnosis of these destructive pulmonary lesions, and that is in regard to the use of exploratory puncture. Exploratory puncture is frequently performed in such cases, but it would be better if it were never done. There are dangers which the records of any large hospital will probably show, and certain of our records do show in the performance of this apparently simple operation. The pathology of abscess or gangrene is such that blood vessels lining the wall or traversing the lumen of the cavity may be unsupported by any tissue, and their injury may be followed by severe and even fatal hemorrhage. A second feature in connection with the more chronic cases is the displacement of the diaphragm upward in consequence of the loss of pulmonary substance and the contraction of connective tissue. In some cases the upper level of the diaphragm is elevated far beyond its normal position into the thoracic space, and its perforation by an infected instrument may lead to fatal peritonitis. This last danger is not confined to chronic abscess or gangrene, but is common to all chronic inflammatory lesions in which replacement of normal structures by connective tissue takes place. It is a matter which should be constantly in mind, not only in connection with chronic pneumonitis, but also with chronic empyema, and in any such condition when thoracentesis is under consideration it is desirable that the exact position of the diaphragm be determined by x-ray examination before an exploratory puncture is made.

In regard to the prognosis of pulmonary abscess and gangrene, the mortality of gangrene may be estimated at about 80% in unoperated cases. The mortality of abscess is probably a little lower than that of gangrene. In 31 of the more recent cases of unoperated abscess in my series the condition at and after discharge from observation has been determined and 22 died, a mortality of 70%. It should be said concerning the outlook without operation in the remaining 20 to 30% that while in many instances there is

relief of the more urgent symptoms, yet there is only uncommonly a complete recovery from the suppurative process. The patient is likely to be continually harassed by the expectoration of purulent material and constantly liable to recurrent attacks of broncho-pneumonia and gradual extension of the pulmonary infection. Complete recovery from these destructive pulmonary lesions without operation occasionally occurs, however, and I have had the good fortune to see this take place in three private and two hospital cases. In all five of the cases there were symptoms of sepsis and cough with abundant foul sputum. The onset was insidious in three, in one the pulmonary symptoms followed the extraction of teeth under ether and in the last case an infected embolus from the hand was the probable cause. The duration may be estimated to have been from about two to ten months. Dullness on percussion, with or without other signs, over a circumscribed area was present in four, while physical examination was negative in one case. X-ray examination was not made in one, but was positive in the remaining four cases, two of which showed suggestive evidence of a pulmonary cavity. Elastic tissue was not demonstrable in one, but was found in the sputum of three cases, and in the remaining case a lung shred was discovered. In three of the five cases I was able to obtain an examination by means of the x-ray after the process had fully subsided, and in none of these could x-ray evidence of any residual disturbance in the lung be demonstrated. In all cases the recovery was complete and the patients are still without cough or expectoration.

One of these recovered cases deserves mention in somewhat greater detail. It was the case of a man of 41 who came to me Dec. 4, 1914, with the history of cough and purulent expectoration for the preceding seven years. He gave the history of having had foul expectoration only since October 15, and this feature of the story is worthy of note and is a matter it is well to have constantly in mind in taking the history in such cases. While the patient may have had a long continued pulmonary infection, it may be possible to elicit from his story an indication of a more recent origin of a complicating destructive process, thus putting a more favorable aspect on an otherwise serious situation. This patient expectorated about a glass full of very foul sputum in twenty-four hours, and during paroxysms of cough his breath was very offensive. There was dullness in the right mid-back, positive x-ray with evidence of a cavity partly filled with fluid which changed its level on changing the position of the patient, and in the sputum no elastic tissue but a lung shred. He had fever and leucocytosis and was constantly losing weight. In view of the progress of the disturbance I suggested, and even rather urged, operative interference. He took the matter under consideration and did not at once accept my advice. He soon began to improve, and in about

two months from the onset was completely well and without cough or expectoration, a surprising result, especially in view of the pulmonary symptoms preceding the more recent origin of the abscess. X-ray examination by Dr. W. J. Dodd, on March 11, 1915, three and one-half months after the first observation, showed no evidence of the previous trouble.

Such an experience as this is, of course, exceptional, but the chances of spontaneous resolution of pulmonary abscess, slight though they be, must be taken into consideration, and make it desirable, if possible, to keep these cases under observation for a time to determine the tendency of the process for better or worse. It may in general be said that to a limited degree the cause has a bearing on the outlook, lobar pneumonia or trauma being relatively favorable, the inhalation of foreign bodies or the lodgment of infected emboli in the lung being less hopeful for recovery.

Regarding treatment, it is important to remember that while surgery offers the greatest hope it is not to be applied indiscriminately to every case and that other and simpler measures may be expected to be of distinct advantage. All patients with symptoms of sepsis should, of course, be abed. An abundance of nourishing food and fresh air are of importance. The toxemia and general sense of ill-being may be lessened by cautioning the patient not to swallow his sputum. The effect of posture should invariably be given a thorough trial. Evacuation may be favored if the patient lowers his head over the edge of the bed during a paroxysm of cough. At stated intervals and for a certain period the patient should lie with the affected side uppermost with the purpose of draining the pus into the trachea. Elevation of the foot of the bed for a time night and morning, the patient meanwhile lying at full length on the back or abdomen and without a pillow, should be tried.

In deciding between expectant treatment and surgery, the clinical aspect is of prime importance. The general appearance of the patient and the degree of sepsis, measured by the temperature curve, the pulse rate, sweats, chills, and the white count, are valuable guides. A daily record of the cough and the amount of expectoration are important for the estimation of progress. Persistent septic features, with an increasing amount of sputum and abundant elastic tissue or lung shreds indicate an advancing lesion. The chances of surgical relief diminish with the lapse of time. Of 31 operated cases, in 19 with a previous duration of nine months or under, 5 died and 1 was not relieved, the result thus being unsuccessful in about one-third of the cases; while of the remaining cases, 7 were relieved and 6 cured, a favorable outcome in about two-thirds of the cases. Of 12 cases with a previous duration of nine months to two years, 5 died and 2 were not relieved, the attempt at relief thus failing in about three-fifths (58%)

of the cases, while the remaining 5 cases obtained notable relief, but as yet no permanent cure. A more extensive lesion, multiplicity of foci and the presence of dense induration about the affected regions probably account for the less favorable result in the more chronic cases.

The indications for or against operation are difficult to formulate and each case must be decided on its merits, but as a general rule it may be stated concerning the acute cases that in the presence of a small process, without marked symptoms of sepsis, with purulent and not foul expectoration and without a large amount of elastic tissue or lung shreds, an expectant policy may be followed. If, after observation for three to four weeks, recovery or marked improvement does not occur, operation should be considered. Operation is indicated, on the other hand, with an extensive process, marked sepsis, putrid sputum, and abundant elastic tissue or lung shreds. The exigencies of the individual case determine the propriety of operative interference in cases which have lasted for months or years. The condition may be intolerable to the patient or so menacing to life as to justify surgical intervention, even though little more than partial relief may be expected. Circumscribed, inextensive and single lesions offer a greater hope of success.

The advantage of surgery over the expectant treatment of abscess or gangrene cannot be estimated alone by the mortality returns, which though sufficient to prove that surgery is the more effective, do not tell the whole story. The observation of cases before and after operation, even when the outcome is unfavorable, oftentimes indicates that the operative procedure was justified, as indicated by diminution in the degree of sepsis and the amount of foul sputum, and if performed earlier or under more favorable local conditions might well have been successful in affecting a cure.

II.

THE RECOGNITION OF PLEURAL DISORDERS BY X-RAYS, WITH SPECIAL REFERENCE TO EMPYEMA.*

BY PERCY BROWN, M.D., BOSTON.

It occurs to the writer that, perhaps, the chief value of any contribution to a symposium lies in its brevity. Circumstances make it possible for him to attempt to demonstrate his assertion, for it so happens that, concerning the matter of pyogenic infections of the pleurae, to which he purposes to confine himself, the diagnostic help afforded by x-rays plays a part secondary to the usual forms of clinical investigation. Only occasionally is the condition difficult of clinical diagnosis, and its chronic existence may be often

inferred from mere inspection, amplified by the art of deduction. On the other hand, x-rays used as a means of recording the extent of the process, the neighborhood disorders which it engenders and the progressive effect of appropriate treatment, offer a field of which the fertility is not always taken advantage of.

There are surely reasons for this, and some of them, possibly, merit a moment's discussion. The chief of them all, it seems, is the difficulty of bringing the patient and a proper source of x-rays into immediate corollation, except in favorable instances where the patient may be in a hospital. This applies less to the acute, dry or plastic pleuritides, since it is hard to see where roentgenological examination here can add to the information to be obtained by auscultation and percussion. In acute cases, however, it will be found, as shown by experience, that the time spent with the fluoroscopic screen is not wholly wasted. The effusive stage which, as it increases the amount of its inflammatory product, bringing with it the respiratory distress and increasing subjective weakness, seems to widen the chasm of difficulties attendant upon the ambulation of the patient. The precursors of purulent pleurisy, such as a pneumonia or a focus of profound sepsis, may, likewise, have reduced the patient to a condition which contraindicates strongly any gross disturbance of him, such as removal from the sick room or ward.

It is a happy fact that, in the acute or sub-acute pleural disorders, the employment of fluoroscopy, or visual examination with the screen, far exceeds in value the production of graphic records upon plates or films—so-called radiography. If x-rays are to be used at all in the dynamic stages (and, be it said, they can in such cases be used only in a way accessory to the incontrovertible methods of physical examination we all know), it is largely the limitations to normal respiratory function we wish to observe. Even if effusion has appeared and is beginning to occupy the domain of the retreating friction-rub, we can largely deduce its composition by observing its readiness to comply with hydrostatic laws. These observations are to be made by fluoroscopy alone.

Since, therefore, fluoroscopy is to be desired at times in non-ambulatory cases, while radiography as often goes a-begging, one must surmount the difficulty of producing a transportable fluoroscopic apparatus. As a matter of fact such a task is relatively easy—much more so than transportable radiography is. In the acute cases, as has been said, the phenomena of physiologic motion, or of pathologic departure from it, are primarily to be observed. In instances where the by-products of inflammation are accumulated, but where the case is as yet to be maintained in comparative quietude, the effect of posture upon the level of the effusion may be noted roentgenographically, and cooperation, at least, afforded to the hand guiding the aspirating

* Presented before The Massachusetts Medical Society, June 9, 1915.

needle. Here also the roentgenologist may even venture to afford material help to auscultation and percussion, with due respect, especially if pyogenesis has set in and the effusion becomes sacculated or interlobar.

Besides, fluoroscopy, in the cases of those who are acutely sick, disturbs the patient no more than a thorough investigation by auscultation and percussion often may. The extreme necessities of the present war have become mothers to inspirations of invention resulting in marvels of mechanical convenience by which x-rays may be used in the field and at the bedside, and a thoroughly transportable fluoroscopic apparatus for use in more peaceful surroundings is soon to be, it gives one pleasure to say, an accomplished fact.

Roentgenography comes into its own, so to speak, when the subacute or chronic cases are to be considered, or when the variant dispositions of effusion are to be observed. The chronic adhesional pleuritides, which may include the empyemata, may be classed in this gamut. To the writer's mind the deformities of the pleura are to be considered of equal importance to those of the upper respiratory passages, to those of the digestive apparatus, and to those of the articular structures. The respiratory ravages produced by the empyemata of childhood may complicate, in a way purely mechanical, the future existence of the individual. The parietal contractures and the malposition of the ribs make a determination of the amount of usable lung a matter of great difficulty by auscultation and percussion, even to the most sensitive ears. The proportion of serviceable vesicular tissue beneath non-expanding chest walls is by no means difficult to determine by x-rays, nor are the limitations of such tissue in inspiration and expiration. The same handicaps are thrown in the path of auscultation and percussion when it becomes necessary to determine the displacement of neighborhood viscera within a deformed chest or beneath organized exudate. This applies especially to the heart. By x-rays, rarely is the cardiac-shadow lost behind that of an effusion, while it will be visible through the most dense exudative organization.

To him who may be more interested in therapeutics and its results, much information is afforded by x-rays with respect to the phenomena of resolution, absorption, expansion, and the general or partial resumption of normal state or function. Especially gratifying to see are the evidences of the mastery of Nature over the apparently crippling consequences of a purulent pleuritis.

In order that such may be seen by this company and that it may be spared a humdrum demonstration of pleural effusions of all sorts and types, familiar to every eye and ear, it is the writer's purpose to present to you the end-results as demonstrated by x-rays in three cases which differ somewhat in etiology and in nature.

The first is that of B. A., a child between four and five years old, who first came under observation during the middle of last December. She presents no history of the exanthemata or of other infectious process. She does, however, give a history of persistent nasal catarrh and a multiplicity of head colds. On physical examination, her tonsils are slightly enlarged, but seem not to be the hosts of acute infection. She has a few small cervical glands. Her lungs present a slight dullness in the left back from the mid-scapular line to the base; in the axillary line from the fourth rib to the base. Over a small area as large as a silver dollar, breath sounds are diminished and expiration is slightly prolonged and high pitched. No rales are heard and no dullness is perceived. The sign of D'Espine is not present. A provisional diagnosis is made of lobar pneumonia. A few days later the dullness extends over the entire left lung and dullness to flatness from the mid-scapula to the base. Bronchial breathing appears about the base. On the twenty-sixth day of the month, the lower left chest is flat. The respiratory murmur is lost — the bronchial breathing is distant. The heart is percussed as four centimeters to the right. The diagnosis is pleuritis with effusion. On the same day the patient is aspirated and one ounce of pus obtained. The child is then referred to surgical care. The following day the rib is resected by the classic operation. A large quantity of yellow pus with cheesy flakes is obtained. In this specimen there is reported the existence of the pneumococcus. Drainage is instituted. Two months later the subsequent history describes a period of somewhat sluggish drainage and a subsequent operation for producing it more freely. The second record shown you is that of this child six months later, after complete closure of the wound and after a course of therapy directed toward exercising the lung by means of Wolff bottles, horns and the like. The change, you see, is marked and distinctly for the better, but presents otherwise no especial interest. In short, the case is one which is typical as showing the value of subsequent examinations and ultimate permanent records. Such comparative records, at once all-embracing and graphic, can be obtained only by roentgenography.

The second case is that of F. T., a girl of eight, first seen in September of last year. She gives a history of previous empyema which has been draining for a long time and, of late, she complains of more cough and of cold sweats. She presents a considerable degree of thick, yellow expectoration. On examination, her tonsils are slightly enlarged and her lungs present a diminished expansion, with especial reference to the entire right base. A gross degree of flatness obtains over the area of the drainage tube. Vocal fremitus is absent as well as breath sounds. The operation, naturally, consisted of a reestablishment of drainage. A month later the operation of decortication was done and the visceral pleura was found to be holding the lung tightly back. This was incised and freed. The etiological factor was found to be the staphylococcus albus. The length of duration in this case has, apparently, produced much thoracic deformity which, by x-rays, is more apparent anteriorly than behind. The first record shows the causation of the dullness to flatness about the original drainage tube. The case has recently been seen by the writer with reference to the end-result. As one may easily see in the next record, nature has

made the best of a hard task. Especially posteriorly is the degree of resolution and repair most apparent.

The third case is that of W. J., age six and one-half years, who was seen in November presenting the following history: a pneumonia was sustained at the age of four, followed by empyema. Three months later a rib resection was done. Five months later, a second operation. Even after the second operation an undiminished discharge persisted. General health became poor and appetite meagre and the bodily weight diminished. At the time of hospital entrance vocal fremitus is absent over the lower two-thirds of the left side; flatness on percussion. Voice and breath sounds are absent. The right lung gives good resonance. The finger tips show most beautifully the chronic osteoarthropathies of pulmonary origin. The operation consisted in a new resection. The old sinus was made freer. A few days later the boy is observed not to be doing well. The discharge is small. The left upper lobe presents bronchial breathing and dullness on percussion. Three days later the crisis of an apparent secondary pneumonia occurred and the sinus discharge markedly improved in amount. The next month the boy continued slowly to get better. The amount of discharge is diminishing slowly. Blowing exercises have been instituted.

This boy was handicapped not only by low physical resistance, but by the onset of a secondary pneumonia, yet the degree of expansion which has taken place in his case is remarkable, especially when comparison is made between the records now to be shown. The first record was obtained in November of 1914 and the last but a few days ago.

Thus it will be seen that the function of x-rays by no means ceases when the initial diagnosis is made or when secondary diagnoses are made. They are most properly an agent by which may be observed and recorded the degree of handicap with which the patient has forthwith to contend. As such, their function is far more important than as a desirable but unnecessary and secondary adjunct to a diagnostic procedure as old as the day of Laennec.

To him who prizes the graphic evidence of pathologic processes, as well as to him who cherishes the gratifying evidence of his own good work, a dependable record by x-rays is not only a thing of beauty, but becomes a joy forever.

III.

PNEUMODYNAMICS OF EMPYEMA.*

By FREDERIC J. COTTON, M.D., BOSTON.

THERE is a whole physiological literature centering around the essentially simple condition of a rigid thoracic cage, varying in content with a moving diaphragm, containing an elastic, collapsible body—the lung—held from collapse, primarily, by the air-tight empty pleural cavity.

Surgically, the points of interest are less in number, though even the surgical literature is rather vast. What we wish to know for practical surgery may be summed up as follows:—

1. What happens in pleural effusion?
2. What happens in pyopneumothorax, simple or valvular?
3. What happens if we tap one or the other?
4. What happens if we open the chest?
 - (a) With a small opening.
 - (b) Wide open.
 - (c) Right and left.
5. What factors govern the varying collapse of lung?
6. The clinical features of lung collapse.
7. The effect of intratracheal insufflation.
8. The effect of the now nearly obsolete positive and negative pressure chambers that have cost so much work and thought.
9. The question of drainage.
10. Reexpansion of compressed lung.
 - (a) Immediate, as in empyema operations.
 - (b) Later, by valves or siphon or suction.
 - (c) Expansion by cough, Wolff bottles, etc.
11. Physics of chronic empyema.
12. Physics of Schede or Oestlander operations.
13. Physics of decortication.
14. Physics of heavy negative pressure with or without decortication.

In the normal chest there is rhythmic, alternating, increase and decrease of cubic contents, as diaphragm and chest muscles act. If air goes in and out freely, neither positive nor negative pressure reach any high grade; with closed glottis, the pressure variation is far greater, of course.

In the pleural cavity tension varies from about 4.5 mm. Hg. to 7.5 mm. (Heynsius); according to Aaron (who did his experiments on man) this pressure varies from 3.02 mm. at the end of expiration, to 4.64 mm. at the end of inspiration; this under quiet conditions. Forced respiration is said to give readings as low as 30 mm. Hg.

Not less than five factors come into play in determining the intra-pleural pressure: the positive pressure of expiration; the negative pressure of inspiration; the elasticity of the lung (a factor in negative pressure, as far as it goes, measured to about 3 to 7 mm. of mercury); lymphatic absorption, that clears the cavity of fluid, but is actually a result of the pressure factors rather than an active agent in determining pressure, so far as we know; and last, but by no means unimportant, the "surface tension" of the great pleural surfaces, tending to preserve their contact.

A mere leak in the parietal pleura does not produce collapse. We are told that this depends on the size of the parietal leak; that such a leak may not exceed in cross section the size of the lateral primary bronchus, without lung collapse. This may be so in times of quiet respiration, but all of us have seen, at operation, holes far larger than any bronchus, filled with lung tissue, sug-

* Presented before The Massachusetts Medical Society, June 9, 1915.

gesting the beginning of that "hernia of the lung," which I know only from the older literature. This is not a question of surface-tension alone, of course. The useful fact to know is that surface tension alone tends to prevent lung-collapse, if the pleura is *slightly* torn. Given a larger wound, the lung tends to retract sharply, unless held by adhesions.

It does not collapse entirely in human cases, as it does in some animals, simply because the human thorax is very broad and shallow, with a short and strong mediastinum between the halves; a very different condition from the *long, lax* curtain in the deep *narrow* chest of most lower orders.

In man, one side of the chest may be full of fluid or of air, with very little effect on the other side. The heart goes over a bit, but the cavity remains, with relatively rigid walls. Inspiration sucks in air, but more than this, expiration pushes air, not only into the trachea, but into the other bronchus as well, and if the glottis closes during expiration, two or three times, as with a cough, the other lung fills full!

Commonly with the deep, irregular coughing respiration that these cases show under light anesthesia, the air forced from one lung to the other, under quick expiration, with partial glottis-closure, suffices to fill a collapsed lung *entirely*; sometimes to keep it filled—once a dressing is on—for an indefinite time.

Now to go back to our questions.

What happens in case of pleural effusion?

Fluid collects and until a considerable mass collects, the tension question is practically unaffected; the lung on this side grows less in volume, largely through collapse of the lower lobe. Lung elasticity and consequent retraction keep the tension balance nearly even. The upper level of the fluid (as Garland of Boston showed in the first paper I know of on Pneumodynamics) is not a level, but a curved line. The x-ray shows a similar irregularity in the upper level; there is, in fact, as the x-ray shows, *not a definite level at all*, but a gradual diminution in wedge-shaped cross section, between lung and chest wall, with a sort of flat "S" shaped profile. As the fluid, serous or purulent, increases in amount, the diaphragm *sinks* under the weight, and presently the intrathoracic pressure on this side becomes continuously positive. Heart and other mediastinal structures are pushed over well beyond the mid-line. This is the stage of dyspnea and eventually of cyanosis. One lung is enough to breathe with, if the patient is quiet, but this one lung must be undisturbed, and one lung under pressure is not enough for comfortable function.

In "pneumo," which is always "pyo" pneumothorax, the fluid weight is less; the diaphragm is less pushed down; cross pressure on the other side is less, as a rule. Physical examination reveals the condition pretty clearly,—a horizontal level between denser fluid below and air-filled pleural cavity.

X-rays show fluid below with air above, but in this case the line is not Garland's line, but a *level* between water and air,—*horizontal*, varying, of course, with the posture of the patient.

In all cases of pyo-pneumothorax, the pressure must, I think, be positive, but this pressure is ordinarily slight. Given a wide-open pneumothorax opening into the lung, the pressure must be zero, but this is not the condition that occurs in fact. The opening is commonly small (at least at first), and air is pumped into the pleura more easily than it gets out.

In one case of my own, a policeman, shot full of birdshot by a "yegg," and in *extremis* from pneumo-hemo-thorax, with obvious pressure, a simple tapping of the over-filled pleura brought his heart back to mid-line, saved the situation, and (as the valve action had ceased) led to his prompt recovery.

In another case I saw with Dr. Bapst Blake, a free opening of the chest saved, at least for a time, a tuberculous patient, in whom a valve-like lung perforation had led to a distention, constantly increasing, that threatened life.

What happens if we tap a chest?

Years ago I punctured a chest full of fluid with the knife point, intending to go ahead in the usual way. Before more than 1 to 2 c.c. of fluid had escaped, respiration stopped, and despite all restorative measures, was not re-established in this case. It was a case of extreme positive pressure with cyanosis from total emphysema; a rather desperate case from the start.

What happens in such cases of vasomotor death, no one knows, of course, but I suspect there is a factor of safety in securing the relief of *extreme positive pressure* with a needle, *without anesthesia*. The case noted was lightly anesthetized, and even light anesthesia disturbs reflexes.

More cases have died from simple tapping than have gone under from operation on the spot, apparently, yet I think it is safer to lessen pressure with the needle one day, and then excise 24 hours later, after tension conditions have become nearly equalized. In ticklish cases, I have often done this: with careful removal of fluid by aspiration, the patient may be brought to the operating room in much better shape. There is, of course, no considerable toxic absorption in the interval after the tension is reduced.

What happens when the chest is opened?

In the normal chest there is some sucking-in of air, but not much, if the hole is small. If much fluid is present, a jet of fluid is promptly thrown several feet with the first expiration. As a rule, the pleural reflex excites a cough and expulsion of fluid is violent for some time. Theoretically, if the parietal hole is large, there should presently be a collapse of lung again. In fact, there is nearly always sharp reexpansion and the collapse does not occur till hours later. If the wound is well dressed, it often does not occur at all. Real collapse must occur if double

empyema is operated on, both sides at once; hence the practice of opening one side and only tapping the other. With efficient valve or suction dressings, the simultaneous operation, or at least opening one side after opening and dressing the other, should be quite safe.

What are the factors governing collapse of lung?

So far as empyema cases go, there are: previous collapse and compression, long continued, then unimpeded access of air from without, on the one side, and respiration with partial glottis closure on the other, supplemented by intentional or accidental valve action at the wound.

What are the symptoms of lung collapse?

In empyema there are none. Rarely does the lung collapse at any time, more than it has been collapsed by the effusion. Such vaso-motor troubles as arise are due to tension changes and to the reflexes of pleural irritation, not traceable to lung collapse.

As to intratracheal insufflation. Theoretically desirable, it has in fact, no place in empyema cases. The deep anesthesia necessary, in order to intube the trachea is too deep for safety in these cases. Moreover, the operation for empyema—rib resection and all—should be over in less time than it takes to anesthetize and to insert the tube for insufflation.

Positive pressure apparatus has no place here. I should hesitate to increase intrathoracic pressure in most cases; the heart load is heavy enough as it is! Neither positive intrathoracic nor negative external pressure are in the least called for, at the time of opening.

Next comes the question of drainage. Most important of all (next to making a hole) is the cleaning out of the cavity, and here is where many operations fail. In certain cases of streptococcus type, the fluid is thin and a small hole is enough. As a rule, however, we are dealing with the pneumococcus and with the massive fibrin layers that characterize this infection. If not removed, these masses inevitably clog any drainage, as they gradually disintegrate after about the third day. It is the presence of this fibrin that makes the mere insertion of a tube ineffective. Every empyema that will stand three minutes of operation, under light anesthesia, should have a resection of three-fourths to one and one-half inches of rib and an opening into the pleura big enough to admit a finger to sweep about and loosen the adherent fibrin masses. These may be fished out, or the patient may be so turned that the hole is at the lowest point. He will then cough out his own fibrin, and we can put the tube into a cleared cavity.

The old scheme of washing out the cavity is alluring, but not to be allowed at operation or later. I have myself seen two cases of dangerous collapse from irrigation, and there are recorded so many cases of such collapse, fatal in so many instances, that there can be no argument about the matter. What happens pathologically is not quite clear; it is, clinically considered, a vaso-

motor affair, and the fatal cases die a "brain-death," long supposed to be embolism. Autopsies have never shown embolism, up to the time I looked the matter up. Let us call it the vaso-motor effect of a pleural reflex. At all events, it is too dangerous to trifle with; we may not irrigate!

As to the exact point for drainage, it does not seem to matter much. The Children's Hospital series I looked up long ago seems to prove double drainage of no sort of value. Whether we drain at the eighth rib or the eleventh is not important. We should drain behind, and the scapula is too low for drainage above the eighth. Very low drainage is interfered with by the ascent of the diaphragm during healing. Mechanically it doesn't seem to matter! Drainage depends on pressures, not primarily on gravity, and an opening at the level of the 8th, 9th or 10th ribs behind fulfils all requirements. I usually resect the 9th just below the tip of the scapula.

As to the tube, the spool tubes (Fowler's tubes) are neatest, but usually do not fit. Two tubes clog as easily as one. My own choice is a tube not less than one-third, or more than three-fourths of an inch, inside bore, fenestrated, reaching well into the cavity, not too long (2 to 5 inches, according to sizes of patients, and held by a safety pin outside the chest).

As to the dressing, it all comes down to a word: *drainage is best accomplished by whatever best promotes expansion*. We have here no ordinary cavity drainage: pus does not drivell out, but is, or should be, *pushed out* by the re-expanding lung!

The question of most importance then is that of re-expansion. And the question of re-expansion is the question of negative pressure. I believe absolutely that *most empyemas get well by accident*; get well because a sloppy, pus-soaked gauze dressing is a very fair valve.

For thirty years past, this problem has been rediscovered and all the means we have today have been reinvented, periodically. I did it all in 1900-1901, and was much shocked to find that Perthes and Revilliod had done it years before. It has all been done since, also.

There are many ways of getting negative pressure in the pleural cavity. The simplest is the wet dressing valve. A little better is the late A. T. Cabot's valve, dating back to the '80's, which was a flap of rubber tissue or gutta percha over the tube, held close by a "doughnut" dressing outside. Mechanically better is the siphon scheme, developed especially by Perthes, in which a trocar carrying a tube inside it is thrust in and the trocar withdrawn, leaving the tube *in situ*, forming a permanent drainage with siphon suction. Except that it does not solve the fibrin question, this would be ideal; in fact it is practically worthless.

The formal valve dressings we shall return to presently. For the moment let us take up the more exact negative pressure apparatus.

FIG. 1.—Suction Apparatus.

The difference between the levels *a* and *b* should not be over 20 inches. At about 30 inches, hemorrhage begins.

In 1900 I worked out and used at the Children's Hospital an exact apparatus of this sort, consisting of a tube in the wound, passing through and sealed to a square of rubber dam, covering the opening and the wound; held flat by adhesive straps, so placed at each corner as to produce light tension in the square of rubber and prevent wrinkling; held adherent by a film of glycerine between skin and rubber, with a tube leading from the drainage tube to a "catch-bottle" for pus; a bottle from which another tube led to a bottle serving as a negative pressure chamber. From this bottle, at the bottom, was a tube leading down to a pan of water. In the cork of the bottle was a tube connected with the bulb of a Davidson syringe. The difference between level of the fluid in this reservoir bottle and the level in the open pan below, was the measure of the negative pressure tension actually exerted on the lung. This tension could be increased by a squeeze or two on the syringe bulb.* I used this on twenty odd cases. It is not hard to handle, and I learned some facts.

1. Tension corresponding to a column of over 30 inches of water often produces pleural hemorrhage.
2. A column of over 20 inches is never advisable even in obstinate cases.
3. Ten inches is ordinarily enough.
4. Negative pressure increases transudation; the pus grows thinner but more in amount.

* This is almost exactly the scheme that I later found described by the Swiss surgeon Revilliod.

5. Absolute reëxpansion does not secure prompt healing though drainage be perfect. In cases with great prostration and low nutrition, even this exact apposition of surfaces may have to continue for weeks before we are secure against recurring collapse, when tension is removed.

This exact negative pressure is the ideal both as regards drainage and reëxpansion. It is a troublesome affair, however, and most nurses are a little dense about it.

From a practical point of view the valve is often efficient in convalescence, and in many cases from the beginning, if the patient will co-operate with us. The valve produced by sewing a skin flap over the end of the tube does not appeal to me. Theoretically, I object because it drains pus under the skin instead of outside it; practically, in all the cases in which I have seen it used, it failed to work—as a mechanical proposition. If we really want a valve, let's have a real valve!

FIG. 2.—Valve Dressing in Situ.

All one has to do is to stretch a square of rubber dam over the tube end, *guy* it *under slight tension* with an adhesive strap at each corner, run a little glycerine under it and put on a swathe. That's all! The rest is mostly up to the patient. If he coughs or breathes hard, he will make the valve efficient; if he is languid, we give him the well known Wolff bottles to blow. Let him make it his life work, for the moment, to blow a red fluid from one bottle to the other, and his valve will work and his lung will expand.

The question is constantly under discussion of the treatment of chronic empyema. Leaving aside for the moment the indisputable fact that chronic empyema represents the results of in-

competent treatment of acute empyema,* let us see what is to be done with the chronic cases.

The favorite operations have been those of Oestlander and Schede. Both these are frankly deforming operations, applicable only to cases in which reëxpansion is despaired of; in which the lung is "given up." The operation is then one simply to enable the closure of a rigid-walled cavity by removing the bony support of one wall and letting it collapse. I can see where it may be admissible to do this is a cavity communicating with an open bronchus. There is nothing else to do in such cases, though I hope we shall presently have something better to offer than these frightful operations with their deforming results, to say nothing of the still high mortality.

Delorme's operation of decortication (later rediscovered by Fowler and tagged with his name in this country) offers more; gives a chance for the sick lung to reëxpand. Sometimes it does this without further ado—sometimes it does not. If it does not, it is our duty to aid reëxpansion by using negative pressure. Negative pressure in my hands has been so successful that in a considerable series of empyema cases (100 to 150) I have done no Schede or Oestlander operations, and but one Delorme operation, and even in this case, utilized suction apparatus and valve dressings to get complete cure. In one case, of many years' duration, with a leak in the lung, I have proposed a Schede operation,—proposal declined. This series includes one case of three years' duration, and a number of cases lasting many months before I saw them.

I believe that proper utilization of our knowledge of pneumodynamics, proper and intelligent use of negative pressure methods of various sorts, will leave us with a lower mortality, with fewer—nay, with almost no—chronic cases, and will furnish us with adequate means of treating such chronic cases as come to us without frequent resort to the radical and deforming operations of the past.

* Save in the rather rare cases in which a leak in the lung precludes proper treatment by negative pressure.

IV.

THE TREATMENT OF CHRONIC EMPYEMA.*

By F. B. LUND, M.D., BOSTON.

THE treatment of chronic empyema offers to the surgeon problems of the greatest interest and difficulty. The longer one's experience with this disease, the more one is struck with the variation in the problems presented. Encapsulated or localized empyemata present problems very different from the cases which occupy practically the whole chest, in which the lung lies in

the costo-vertebral gutter, occupying often an inconceivably small space. Encapsulated empyemata may be anywhere in the chest; high up against the outer wall, between the inner surface of the posterior lobe and the vertebral column,—a position in which it may easily escape our diagnostic efforts,—between the lobes of the lung, between the inferior surface of the lung and the diaphragm; and in these various positions, require varying incisions and methods for their treatment.

The principles of the treatment of encapsulated empyema when chronic are no different from those of the general variety; but owing to the smaller size of the cavity, the problems presented are usually more simple.

The commonest causes of chronicity in empyema are: 1. Too long delay in the primary operation. 2. Inadequate or ill-placed drainage. Drainage, in the writer's experience, is likely to be inadequate when attempts are made to apply suction apparatus for the maintenance of negative pressure in the chest. In these forms of apparatus a smaller tube is apt to be employed than is the better practice, and while pneumothorax may be prevented, occasional plugging and backing up of pus are unavoidable, and these do more harm than would the admission of air in connection with a larger tube and drainage opening. The employment of a suitable valve, by the use of rubber tissue, or, as the writer prefers, of a valve of skin over an obliquely placed tube, to prevent the inrush of air into the chest cavity during inspiration, the writer believes, has an important place in favoring the expansion of the lung, and therefore the prevention of the formation of a stiff-walled non-collapsible cavity; in other words, of a chronic empyema. As this matter belongs not to the treatment of chronic empyema, but to its prevention, the description of the method of the oblique tube and skin flap will be given at the end of the paper, for the writer believes that he has found it of marked service in avoiding the undesirable conditions the treatment of which is under discussion.

When an acute empyema is opened and the pus evacuated, in ordinary cases we have a cavity left whose inner boundary is the surface of the compressed lung, and whose outer the chest wall with its ribs, intercostal muscles, spine, *et cetera*. It is evident that, if the lung at once expands to its normal size and can be made to remain in contact with the chest wall, the condition will be cured. In early operations, when the compression of the lung is easiest, this will take place; and if the anesthesia is light, or local anesthesia is employed, when the patient coughs at the end of the operation, the lung will come out and fill the opening; and if the inrush of air can be prevented at the same time that free drainage is maintained, the cavity may remain obliterated and the cure be rapid and complete. In old or neglected cases, where the pus has been present for a long time, however, the lung is

* Presented before The Massachusetts Medical Society, June 9, 1915.

covered with a thick coating of partly organized fibrin, which may be a quarter to a third of an inch thick. The surface of this membrane is concave to the examining finger and convex to the lung. It is stiff and leathery, and may be further reinforced by a chalky deposit of lime salts. It may and does so compress and bind down the lung that it does not expand, and after drainage a chronic suppurating cavity remains which can be closed only by the collapse of the chest wall down upon the lung, in such a way as to obliterate the cavity. This collapse in adults is prevented to a large extent by the rigidity of the ribs and cartilages, so that while nature, by the crowding together of the ribs and sinking in of the chest, may produce partial obliteration, a chronic suppurating cavity, though of smaller size, is left behind, and a constant discharge, with fever and malaise, emaciation and asthenia, are present. In children, whose softer bones and more movable cartilages may allow still greater collapse of the chest, chronic cavities may come nearer to obliteration in this way, but the obliteration is usually incomplete, and attended by distressing deformity of the chest, and curvature of the spine toward the affected side.

The earlier operators who attacked this problem all attempted to allow the collapse of the affected chest by resecting its bony walls. This object was attempted by multiple resections of greater or less portions of the ribs which formed the roof of the cavity, and with it the name of Oestlander, of Helsingfors, is associated. His monograph was published in 1879; and while multiple rib sections may have been, and probably were, done by others at about the same time, he deserves the credit of placing it upon a firm basis. He resected varying lengths of from four to six ribs, according to the size of the cavity, in order to allow the chest wall to collapse, and reported his successes and failures. The operation was tried everywhere, and with varying results. There can be no doubt that in the exhausted and febrile subjects of chronic empyema, the operation was sometimes formidable, and that in children permanent curvatures of the spine and collapse of the chest wall had to result. In the unsuccessful cases, the chest wall was found not to have collapsed sufficiently to obliterate the cavity. Such collapse, if it did not take place immediately after the operation, was later prevented by the regeneration of the resected ribs from their periosteum.

In 1890 Schede, of Hamburg, brought out his admirable paper, in which he first presented a real reason for the failure of the obliteration of empyema cavities, namely: that granulation tissue never grew from pleural surfaces, which fact tended to prevent adhesion and obliteration of empyema cavities even in fairly close contact. He also proposed his formidable yet logical operation of the removal of the ribs with the intercostal muscles and parietal pleura over the surface of the cavity and allowing the skin to settle down directly onto the surface of the lung.

This operation, while successful in those patients who survived it, is most extensive and attended by severe mutilation. Except in patients of extraordinary strength and vitality, it may be impossible to accomplish. If successful, it means an extremely marked deformity and collapse of the lung.

In 1893, Delorme, a French surgeon, suggested excision of portions of several ribs, sufficient to get the hand into the chest, to allow the peeling off or decortication of the thick, leathery layer of fibrin which covers and binds down the lung. He showed that by slitting the membrane longitudinally and inserting the finger under it, it may be peeled back, exposing the fresh, raw, bleeding surface of the lung. After it is thoroughly peeled back, and as far as possible removed, the patient at the close of the operation is allowed to come out of ether, and when he coughs the lung expands and fills the cavity of the chest; sometimes coming completely in contact with the chest wall, sometimes not. A tube is then placed for drainage of blood and serum, and a large adhesive dressing applied. This large adhesive dressing, if it can be left on for two or three days, becomes soaked in serum at once, and acts as a fairly efficient valve to prevent the admission of air in inspiration, so that when it is removed the lung may remain adherent to the chest wall. This operation was performed at about the same time by Fowler, in this country, but it seems to me on review of the evidence that Delorme reasoned the matter out and applied the principle intelligently, while Fowler blundered into it and did not know what he had done till afterward. However, the principle became gradually established, and Dowd, Lloyd and others reported its successful employment. Ransohoff advocated, instead of decortication, a series of multiple criss-cross incisions through the thickened pleura to allow the lung to expand.

Beckman, from the Mayo clinic, has recently published an interesting account of several successful cases.

The reasons why I personally prefer decortication I have given in a paper published in 1911. I have since that time seen no reason to modify the technique therein advocated. My own incision and rib resection for acute empyema is performed in the posterior axillary line and concerns the ninth or tenth rib, or both. With the primary incision in this situation, the empyema becomes chronic and decortication is necessary. If we start from this point to open up a cavity extending vertically the incision must be carried upward, and an inch or two of the eighth, seventh, sixth, and fifth ribs resected, and the pleura cut through; then the ends may be retracted, the cavity inspected, the hand introduced, the pleura incised with the knife followed by long scissors, and peeled away.

In case the primary drainage opening is further in front, say the seventh or eighth rib in the anterior axillary line, the necessary opening may

be made by carrying the incision backward and upward in the intercostal space and employing the rib retractor, as recently suggested and practised by Dr. John Homans. The wide springing apart of the tissues stiffened by long-continued infiltration may, however, cause serious embarrassment of respiration; and personally I think the result is attained more simply and with less shock by carrying the incision upward across several ribs, resecting an inch or two, and cutting across the pleura between. The bleeding from the intercostal arteries gives surprisingly little trouble, and may be easily controlled by clamps. However, the method of getting at the thoracic pleura which may suit one man will not suit another, and the main point is to get at it and get it off.

The employment of intratracheal anesthesia has been of the greatest benefit in these cases of chronic empyema, as it enables us to blow up the lung during the operation, to see the effect of what has already been done and determine as to the necessity of further procedures. The lung may thus be held against the chest wall till the operation is completed and the dressing applied, so that we are not dependent upon the spasmodic coughing of the patient, which works by contrast both irregularly and inefficiently.

In an interesting presentation of the subject by Dr. John Homans mentioned above, he refers to the fact that repeated operations are frequently necessary. This has been true in my experience. Decortication may be only partly successful and have to be followed by rib resection over a small area that refuses to heal. Rib resection may have to be supplemented by decortication. In the after-treatment, the use of the blow bottle, and the rubber valve proposed by Cotton, should not be neglected. A device which I have employed successfully in two or three cases is to leave several patches of membrana on the lung, while peeling off the rest, and passing catgut sutures through them as holding points, and suturing the viscera to the parietal pleura, generally carrying the catgut around a rib.

Schede's principle that the pleural surface does not granulate is met by decortication, in that the actual visceral surface layer of the pleura, which consists of a single layer of cells, is scraped off, leaving a bleeding raw surface. The parietal pleura also ought to be removed to bring the granulating surfaces into contact. Personally, I have found the attempt to peel the parietal pleura off the concave, rigid, inner surface of the chest too difficult, bloody, and exhausting a procedure, and so far have succeeded or failed without it.

Of recent years, considering the large number of acute empyemata at the hospital, we have had a surprisingly small number of chronic cases to treat. This is due, first, to early operation; the cases are frequently now transferred from the medical side before the exudate has become more than sero-purulent; second, to the thorough re-

moval of the fibrin; third, to adequate dependent drainage; fourth, to the valve, either of skin or rubber, applied over the tube; and fifth, to the less frequent dressings during the after-treatment, and the prevention as far as possible of the entrance of air while allowing the escape of the pus.

In a recent case of double empyema on my service, the application of these principles has led to a brilliant success in a case that on one side at least had threatened to become chronic.

In my own experience, as in that of Dr. Homans, multiple operations have been necessary, especially in the long-continued cases of empyema totale, where the cavity has occupied the whole chest. In these cases, multiple operations have been frequently required, and there have been failures and fatalities. In localized chronic empyemata, decortication has usually given most brilliant results, and been successful the first time.

Decortication is not a cure-all or specific. It must be thoroughly and intelligently used, and must be preceded and followed by all the tricks and dodges which experience can suggest to secure lung expansion, except those methods which imply suction apparatus and provide an inadequate drainage opening. It may have to be supplemented in certain obstinate cases by rib resection.

On the whole, however, and properly used, we must regard it as an invaluable method in cases where the later simple methods fail to cure, and the ultra radical methods are sure to kill our patients.

I hope an increasingly large number of surgeons will familiarize themselves with the method and become acquainted with its advantages. It is not a minor operation, to be undertaken lightly; nor is it, on the other hand, of difficult technic. It looks the first time like a bloody and difficult procedure. It requires, among other things, good judgment as to how far to go and when to stop. It gives brilliant results. All of which ought to make it interesting to the surgeon.

I think it may be regarded as fair in this paper to allude to a device of extreme simplicity which has been of the greatest value to me in the treatment of acute empyema, and therefore the prevention of the chronic form, an arrangement which is of special value during the first few days of the treatment, when the maintenance of the expansion of the lung is of the greatest importance, and which in my experience has often secured such expansion as to allow the removal of the tube in three or four days. It consists in the use of the skin as a valve over an obliquely placed tube.

An incision is made over and parallel to the rib, below the one to be resected, and is about four or five inches long. The upper margin is retracted upward to the level of the upper border of the rib above, which is resected. The

tube, just long enough to reach from the lower border of the skin wound into the chest, is cut very obliquely, so that in place the skin lies over its wide opening without being pushed up. The extreme lower margin of the tube, opening outward, is sutured to the lower margin of the wound. The skin flap, formed by dissection, is sutured on either side of the tube to the lower margin of the skin wound, and on inspiration will be sure to suck in over it and prevent the entrance of air. On expiration, the skin is blown outward and allows the pus to escape.

This is very simple and cannot get out of order. When the tube has to be removed, say in four or five days, no more drainage may be necessary as the lung has often expanded. If it is necessary, then or later, one of the rubber valves may be better. For the first few days, however, the skin flap has very great advantages. It cannot get out of order, does not require attention, affords free drainage. The pressure of a tight bandage over it only renders it more efficient. Some of my friends, as well as myself, have found it very useful.

V.

LUNG ABSCESS AND BRONCHIECTASIS FROM A SURGICAL POINT OF VIEW; CERTAIN END RESULTS OF ACUTE AND CHRONIC EMPYEMA.*

By WYMAN WHITTEMORE, M.D., BOSTON.

I HAVE been asked to speak to you on the surgical aspect of lung abscess and bronchiectasis; and to give you certain statistics of end results of acute and chronic empyema.

Several months ago I looked up and published in the BOSTON MEDICAL AND SURGICAL JOURNAL the end results of cases of acute and chronic empyema at the Massachusetts General Hospital.

I traced as far as possible the cases operated on from January 1, 1901, to January 1, 1911.

I was a good deal impressed by the fact that out of 269 cases of acute empyema operated on during this time, there was a mortality of 20%, and that out of one hundred cases that left the hospital alive, 20 became chronic.

Out of 154 of these cases that have been traced to a definite end result, there were 54 that died following operation (giving a mortality of 20%). Of the 100 cases that left the hospital alive, 68 are well at the present time. By this I mean that there is no discharging sinus, no bad effects from operation, and that they are able to attend to their regular occupations. Twenty became chronic. These have a persistent sinus and a cavity with a much thickened pleura as a rule, and are more or less chronic invalids. The remaining 12 have died since leaving the hospital. I was able to find out the cause of death in nine

of these. There was no connection between the cause of death and their empyema.

An autopsy was performed on thirty of the cases that died following operation; 14 died from septicaemia, 5 from pneumonia, 3 from pyemia, 1 from peritonitis, 2 from multiple abscesses of the lung, 1 from defective closure of the foramen ovale and thrombosis of the left pulmonary artery, and in 4 no definite cause was found. The most common cause of death was septicaemia, the majority being streptococcus septicaemia and a few pneumococcus septicaemia.

There were 35 cases of chronic empyema operated on during this period of ten years. I have traced the end results in 23; 15 are entirely well, 4 did not improve by operation, that is, they have a persistent sinus and are chronic invalids. Two cases died following operation, and 2 have died since leaving the hospital; cause of death not known. Of the 2 cases that died in the hospital, one had an autopsy performed, cause of death being adeno-carcinoma of the main bronchus and extensive bronchiectasis.

The various classical operations were performed; 4 cases had an excision of ribs and parietal pleura excised (Schede operation); 2 are well, 2 not traced, no mortality. Five cases had a decortication of the lung (Fowler operation); 3 are well, 1 did not improve, 1 died; a mortality of 20%. Twenty-one cases had an excision of ribs and pleura curetted (Oestland operation); 1 died, giving a mortality of 5%. Seven are well, 2 not well, 2 have died since leaving the hospital. The remaining nine have not been traced. The other cases had minor operations performed, as, for example, the removal of an old drainage tube or merely curetting the sinus. All these cases are well with one exception.

I feel that the subject of bronchiectasis is almost entirely a medical one. However, a certain amount of surgery has been done. I have tried to take a position between the enthusiastic thoracic surgeon and the more or less pessimistic medical man.

I shall not take up the bacteriology, symptoms or diagnosis.

A few of the causes of bronchiectasis are the following: Unresolved lobar and broncho-pneumonia. Stenosis of the bronchus from a new growth in its wall. Inhalation of foreign bodies. Pressure on the bronchus from outside, as, for example, from an aneurysm or mediastinal tumor. In rare cases bronchiectasis follows a chronic empyema.

In the majority of cases the disease is located in more than one lobe. Occasionally it is in both lungs. The cavities vary from a minute size to those as large as a hen's egg. Where the disease is due to the inhalation of a foreign body or to stenosis of a bronchus it is unilateral for a time at least.

Surgery has nothing to offer to those cases in which the disease is in both lungs. But where

* Presented before The Massachusetts Medical Society, June 9, 1915.

it is unilateral, especially if limited to one lobe, the surgeon may feel a little more hopeful of eventual success.

Various surgical procedures have been undertaken. When one thinks of the pathology of the disease, one realizes the hopelessness of trying to establish drainage. This may be undertaken as a last resort in cases of complicating gangrene in order to save life, but the outlook is far from favorable.

Some years ago it was found that certain cases of tuberculosis were benefited by partly or completely collapsing the lung with nitrogen gas, and thus it seemed possible that bronchiectasis might also be benefited by collapsing the lung. This has been done in two ways: by extensive rib resection and by the introduction of nitrogen gas. Neither method has produced many good results.

Extensive rib resection has certain dangers:

1. Sudden collapse and death from disturbance to the respiratory and circulatory mechanism.

2. Through the patient's cough being checked following operation on account of pain, the secretion accumulates and may flow over into the other lung.

3. Spreading of the infection through the whole system, so that the patient dies from a septicemia.

Four cases have been operated on at the Massachusetts General Hospital. Two died following operation. In both cases an autopsy was performed. One case died from a pneumococcus septicemia, the other case showed extensive bronchiectasis and pneumonitis with areas of necrosis in the lung. The other two cases left the hospital alive. One of them is no better, having the same symptoms as before operation. The other case is well. He was last heard from two years and two months after operation.

The introduction of nitrogen gas into the pleural cavity, thus producing an artificial pneumothorax and causing a partial or complete collapse of the lung, has been tried in some cases, particularly in those where the pleura is not adherent.

I have been unable to find any end results of this method. One case has been treated in this way at the Massachusetts General Hospital, but that case has not been traced.

A third method is that of lung excision. This can be attempted when only one lobe is diseased, which is exceedingly rare. The successful cases have followed a series of previous operations that have brought about a contracture of the diseased lobe.

It is the ambition of thoracic surgeons to do this operation in one stage, but up to the present time almost all patients so operated on have died.

The pneumothorax following operation is dangerous. Fluid may accumulate in the pleural cavity, and this may become infected, either from

previous infection or from leakage from the bronchi at the root of the lung.

The whole circulatory and respiratory mechanism is suddenly upset.

It seems better, therefore, at the present time to allow the patient to become accustomed to the change in circulation and breathing by a retraction or collapse of the lung previous to excision.

I have been unable to get any satisfactory end results. Some half dozen surgeons have each reported one or two successful cases. But how many unsuccessful ones they have had I have not found out.

There has been one case at the Massachusetts General Hospital. This was successful. It was operated on in 1909 and reported in 1912 by Robinson. This case had several operations previous to excision of the lower lobe, so that there were many adhesions and the lobe was more or less contracted. The patient made an easy and excellent recovery. Several months after operation he had four small bronchial fistulae. Two of these were successfully closed. Two years later he was in excellent health. In 1913, four years after excision of the lobe, he died in Canada, but whether or not his death had any connection with these operations is not known.

In marked contrast to bronchiectasis I feel that the treatment of lung abscess belongs to the surgeon in the great majority of cases.

The symptoms, bacteriology, and diagnosis I shall not take up.

The chief causes are lobar and broncho-pneumonia. A good many cases are due to the inhalation of foreign matter. For example, the inhalation of blood and mucus during operations on the nose and throat or during the extraction of teeth while the patient is under a general anesthetic. Occasionally a real foreign body has been found. In one of my cases, a child, a small piece of a peanut was found. An embolism from an infected thrombus may become lodged in the lung and thus start the formation of an abscess. Occasionally an empyema may rupture into the lung, but I believe this is more apt to cause gangrene than an abscess. Actinomycosis is a definite cause. There have been two such cases within a year or so at the Massachusetts General Hospital. Occasionally there is a case following abdominal infection.

The diagnosis is entirely in the medical man's hands.

An abscess may be in any part of the lung, although it is said that they occur more frequently in the lower lobe than in any other, and are apt to be near the pleura. But in my limited experience I have not found this to be necessarily true.

The x-ray is extremely important in definitely locating the abscess before operation.

The prognosis depends upon various factors and in each case it must be determined separately. It depends upon the general condition and age of the patient, and to a certain extent upon the location of the abscess; as one situated

in the posterior part of an upper lobe is much more difficult to approach and find than one near the pleura in the lower lobe. It also depends upon the duration of the process, the theory being that an acute case tends to recover more readily than a chronic one, because in a chronic case the surrounding connective tissue may prevent the abscess walls from collapsing. I am not sure that this necessarily works out in actual practice, as I have seen several chronic cases get well as rapidly as acute cases after operation.

The prognosis is better in cases of a single abscess than in those in which there are several. It should be remembered that a complete recovery may occur spontaneously, but this is extremely rare.

I think the general feeling is that if an abscess does not show signs of marked improvement in two or three weeks it should be operated on.

In the operation for lung abscess I believe intratracheal ether should always be used, although cases have been successfully operated on without it. My reason for this is that there is a good deal of danger of making an opening in the pleura and collapsing the lung when, as is very often the case, the pleura is not adherent. One can never tell before operation whether the pleura is adherent or not. By using intratracheal ether this danger is done away with. Besides which the ether can be accurately adjusted, the embarrassment caused by spasm of the glottis, the accumulation of mucus in the pharynx and the dropping back of the tongue are entirely avoided.

Robinson has collected 1400 cases of intratracheal ether from 35 surgeons. Of these, seven died after the operation, of which only two were credited to the method. In one a broncho-pneumonia was induced and in the other death occurred following emphysema, in which it is stated that a rupture of the lung took place, as a result of the tube being forced into one of the main bronchi. Tracheitis and pharyngitis occurred in only 18 cases.

Sometimes the patient while going under ether will cough so severely that he will completely empty the abscess cavity. This latter may be very disconcerting when one is expecting to demonstrate the opening of an abscess.

It is much safer to do the operation in two stages, and quite necessary to do so when the pleura is not adherent. For although the lung may be well sutured to the pleura before opening the abscess, yet there is great danger of leakage of septic material into the pleural cavity that will eventually form an empyema.

A large skin and muscle flap should be turned up and a section from three or four ribs in the region of the abscess removed. The intercostal muscles should then be cut away and the field made perfectly dry. If the pleura is not adherent, and it frequently is not, the lung can be seen moving under it. Two or three sponges are then laid against the exposed pleura and the skin and muscle flap sutured into place. It is not neces-

sary to suture the lung and pleura, but it may be done before laying the sponges on.

After three or four days at the second stage of the operation, the pleura will be found to be firmly adherent to the lung. An incision is made through the pleura and into the lung, and the lung explored for the abscess. One can explore with a trochar, but I feel it is better to use one's finger as the trochar may puncture a vessel and cause severe hemorrhage. When one is lucky one opens into an abscess with frank pus. However, in a few cases an indurated mass is broken into, from which comes foul smelling bloody material, with perhaps a very little pus or even none at all that is visible. A soft rubber drainage tube should be fastened in and the skin partly closed.

Some of the dangers attending operation are: sudden respiratory disturbances, collapse and death soon after the operation; pneumothorax, empyema, or hemorrhage into the bronchi. One case has been reported in which a blood clot lodged in the larynx.

The first few days following operation are often stormy, as there may be considerable shock. The patients frequently cough a great deal on account of the irritation of the tube in the lung. After three or four days this gradually quiets down and in a week or ten days the tube can be replaced by rubber tissue, which will not be so irritating.

The end results of cases of lung abscess at the Massachusetts General Hospital were looked up and reported by Dr. Lord in 1906. Last year Dr. Scudder reported 16 additional cases. I have combined these two reports to get the following statistics:—

There have been 27 cases operated on: 8 are entirely well, 2 did not improve following operation, 2 have died since leaving the hospital, cause of death not known, 8 have not been traced, 7 died following operation, giving a mortality of about 25%. Three of these died from multiple abscesses of the lung, 1 from multiple abscesses of the lung and liver, 1 from multiple abscesses of the lung, liver and brain, 1 from septicaemia, and in 1 case the cause of death is not known.

As a summary I should say:—

First, that although the operation for acute empyema may be a very simple one, yet the results have been far from satisfactory.

Second, that after an acute case becomes chronic, the outlook for the patient becoming a useful member of the community is very questionable.

Third, I consider that surgery has very little, if anything, to offer cases of bronchiectasis at the present time.

Fourth, the surgery of lung abscess is most encouraging, and there are constantly a greater number of cases being successfully operated on.

This, I think, briefly covers what surgery has been able to accomplish along these lines up to the present time. They are subjects in which

more and more interest is being taken, and I think I am not too optimistic when I say that we look with confidence towards future results.

DISCUSSION.

DR. G. G. SEARS, Boston: The pathological conditions which have formed the subject of this meeting may all be grouped under one general heading—non-tubercular suppuration of the lungs and pleura. As it is a surgical axiom that pus should be evacuated, if possible, the problem which these conditions present is whether or not to operate, and when and where.

Since the conservatism of the internist toward surgical procedures has been criticized this afternoon, I would remind the audience that the pioneers in lung surgery,—Lenhartz, Quincke, Mosler and Brauer,—were all essentially medical men who recognized the inability of medicine to cope with these processes and turned to surgery as the only sure means of effecting a cure.

The first essential of successful treatment is an accurate and early diagnosis, for if operation is indicated it should be one of choice and not of necessity. We cannot lift the lid as in abdominal cases and explore the contents of the chest from conviction that there is something wrong within it. A clear idea of the site and character of the lesion is a necessity. I fear that Dr. Brown, perhaps from an appreciation of his own difficulties in interpreting the x-ray findings in spite of, or possibly because of, his large experience, has spoken more flatteringly than is justified of the results obtained by physical examination at the bedside, since the most careful clinical examination must at times leave the diagnosis in doubt, and while the x-ray is frequently not required, it is often indispensable and may lead to a radical change of opinion.

Recent literature seems to show the great value of the bronchoscope. It appears to have been neglected here in Boston, but I hope that we may soon have a corps of men trained to give help in this way in doubtful cases.

What I have to say will be largely confined to empyema on account of its great clinical importance, partly because it is the commonest of the lesions under discussion, and partly because, when neglected, it leads to other suppurative

conditions in the lungs. Its detection is often difficult. As I look back over my own failures I am convinced that they resulted almost invariably from neglect to lay sufficient stress upon three fundamental propositions which almost deserve to be classed as axioms. The first is that unresolved pneumonia is a pathological myth. If the temperature keeps up and the signs persist after due course of time, something is amiss. If we can exclude complications outside the lungs as a cause of fever, *e.g.* otitis media, pericarditis or endocarditis, we arrive at a diagnosis by exclusion of either pulmonary abscess or empyema, and of these the latter is vastly more common. The second proposition is this—that the diagnosis of pleural effusion is made with the fingers, not the ears. The decisive signs of effusion are absence of fremitus, dullness on percussion and displacement of organs, all of which are made out with the hands. Corroborative evidence may be obtained by auscultation, but quite as often the stethoscope leads to confusion, for we may find loud bronchial respiration, loud bronchial voice, not always oegophonic, and even rales.

The third proposition is that when one is in doubt between a pleural effusion and consolidation of the lungs, it is always the former.

These are generalizations, and all of you will recall numerous exceptions, but the point to be emphasized is that under such circumstances the burden of proof is on the physician to show that it is not an empyema. If not completely satisfied he should summon other aids; among these the x-ray is most important, but the value of the aspirating needle should not be overlooked. Repeated punctures may be necessary to discover the site of the pus. I agree with what both Dr. Lord and Dr. Lund have said regarding possible dangers from the needle, particularly in the presence of suspected pulmonary abscess, but if care is taken in the selection of cases more harm is done by not using it than by using it, for an empyema may be of small size and lurk in unexpected places. It may occupy but a small space between the visceral and parietal pleura, it may be interlobar, or it may be located just above the diaphragm. The latter situation adds one other element of difficulty because the symptoms may be chiefly abdominal and simulate those of subdiaphragmatic abscess or appendicitis. In order to illustrate how confusing such a case may be I will give briefly the history of a patient seen a few years ago in the northern part of the state. He was a young man who had been complaining for several weeks of pain over his right hip. At first nothing was found to account for it, but later a large right-sided pleural effusion developed. The temperature curve was so suggestive of pus that the surgeon, who had been called in consultation immediately opened the chest without previous exploratory puncture—nothing but clear serum escaped. After the operation his temperature continued its previous course, his general cond

tion grew worse, and at the time of my visit he was in a very critical state. Physical examination, owing to the free opening in his chest, was of little value so that the diagnosis of the underlying lesion rested largely on the history, which seemed to me to point to an appendicular abscess which had extended upward under the diaphragm, the pleural effusion being secondary to that. As operation appeared to give the only possible chance of recovery the region between the liver and diaphragm was explored but nothing was found except some soft recent adhesions. Failing here, his chest was again opened and a small collection of pus above the diaphragm was found. His temperature then fell and he recovered sufficiently to leave his bed, when a purulent pneumonia developed and proved fatal.

There is one etiological factor causing suppurative processes in the lungs which I do not think has been mentioned this afternoon, namely syphilis, yet it deserves strong emphasis. In spite of the great advance during the last ten years in our knowledge of the disease we have hardly begun to make a clinical application of that knowledge. Most of the cases still pass unrecognized and masquerade under other diagnoses.

Dr. JOHN HOMANS, Boston: So many very interesting points have come out in this symposium that I shall confine my comments principally to the papers of Dr. Cotton and Dr. Lund, for it is with their subjects that I am most familiar.

I am in thorough agreement with all that Dr. Cotton had to say as to the dynamics of intrathoracic surgery. It seems to me that the expansion of the lung after operation in acute or chronic empyema depends on the establishment of a moderate amount of negative pressure. It depends also apparently on the amount of vitality and enthusiasm which the patient has. In other words, a patient adequately drained and with negative pressure applied in some form, may never cough, may lie supine in bed, and make a poor recovery. I have such a patient now who is perhaps getting well, but I am trying to arouse a little enthusiasm, even trying to make him excited, so that he will show a little more interest.

Dr. Cotton spoke of using a long tube for drainage of acute empyema, and I think that this is a very important matter. The tube should go well within the chest,—if not, it very often happens that in the early part of convalescence the lower part of the lung will stick to the chest wall, perhaps above the end of the tube, gradually shutting off the rest of the empyema cavity from outside. I believe that the tube should be left a long distance within the chest wall,—a soft tube, to be sure,—and left in until the large cavity becomes a broad, flat cavity, the flat cavity becomes a broad ribbon, the flat ribbon becomes a narrow ribbon, and finally closes.

As to chronic empyema, I should like to arbitrate between Dr. Lund and Dr. Cotton. I do not quite agree with either, and the arbitrator

should always expect to be abused by both sides. I am inclined to think, judging from the several operations of decortication I have done, that unless the membrane covering the lung is so placed as definitely to hold down the borders of the lung and prevent it from expanding, a matter which Dr. Lund himself pointed out to me once, it is not so very necessary to remove the false membrane which covers the visceral pleura. It is likely that if proper drainage is established such a cavity will close. If the surface of the lung is convex the lung can never expand further unless the membrane is removed.

Nevertheless, I am inclined to think that if cases of chronic empyema were thoroughly drained with a large opening, a large tube placed well within the cavity, and a proper valve applied, that this should be done before the operation of decortication is attempted. If that does not produce the desired result, decortication should be tried. In this I am reversing a belief which I formerly held, or rather, I am not quite sure enough of the indications for decortication to propose it until proper drainage has proved a failure.

As to the access to the cavity, Dr. Lund spoke of an operation, which I have done, of going between the ribs. This I think is dangerous, and do not recommend it, for when the ribs have been spread apart some distance it seems to me there is grave danger of tearing into the mediastinum. In future I should excise several ribs, according to Dr. Lund's method.

As to the failure of granulations to grow in the pleural cavity, that is a very interesting matter. It is apparently a part of a tendency of the thoracic cavity to pour out fibrin in enormous quantity when it is infected. This seems to me to be due to the kind of bacteria which are present, rather than to peculiarities of the pleura, for there is not any difference which we know of anatomically between the pleura and the peritoneum. It is not surprising that this fibrinous exudate forms a thick membrane on the outside of the lung, and being composed of many layers of fibrin it has a very poor blood supply, never organizes well, and will not adhere to an opposing surface, as Dr. Lund has said, for a very long period. This is one of the important matters to consider in treatment. If the cavity is such a shape that it is unlikely to close by any mechanical means, then its walls must be rendered collapsible, or the lung must be made to expand and fill it. In either case the thick false membrane must usually be removed from the lung or from the chest wall if the cavity is to be permanently obliterated.

As to the operation for abscess in several stages, which Dr. Whittemore has spoken of, I think that principle might well be applied to other lesions than abscess. I feel very strongly that in operating on those patients with chronic empyema, who have been sick for a long time, it is better to begin slowly, and if you can get their

confidence and if they are willing to stay in the hospital, operate by degrees, by rib resection first, then exploration of the chest, and drainage. Such patients improve enormously as the result of perfect drainage, and it seems only fair never to impose on them at first any radical operation which is at all likely to be fatal, because these operations are not necessary as immediate life-saving procedures in chronic empyema, though they may perhaps be in lung abscess.

DR. J. S. STONE, Boston:—Empyema in children is essentially the result of poor hygiene. About fifty cases are treated each year at the Children's Hospital. They come for the most part from the more crowded sections of the city, where the children get little fresh air and sunshine. This is in striking contrast with the not exceptional experience of a physician with a large practice in a healthy suburb, two cases in twenty-one years.

Empyema in children is almost invariably a sequel of pneumonia. In pneumonia in children there is very commonly an involvement of the pleura as well as of the lung. The degree of pleural involvement and the power of resistance of the child determine whether an empyema results. The previous health of the child, as well as the care and surroundings during the acute illness are thus important factors in the incidence of empyema.

The empyema may be general, or localized by limiting pleural adhesions. When localized, the ordinary site is in the lower posterior part of the chest. A very few are interlobar. Any localization is possible. I have operated upon one patient in whom the pus lay between the lung and mediastinum, behind the second costal cartilage, close to the sternum.

The possibility of the direct extension of empyema beyond the pleural cavity and of metastatic foci of infection must be borne in mind.

Occasionally, of course, empyema is seen as a part of an overwhelming and obviously fatal infection of the serous membrane,—pleura, pericardium, meninges, joints, peritoneum. No treatment can avail in such cases.

During the convalescence from an ordinary empyema a metastatic peritonitis may develop very suddenly. In such instances the peritonitis is not secondary to disease in any abdominal organ. Such infections are easily overlooked at first because the explanation of the fresh symptoms is sought for in the chest. Vomiting, abdominal pain and tenderness, wherever located, are the symptoms upon which the diagnosis must be based and prompt surgical intervention undertaken if disaster is to be averted.

Such cases differ absolutely from those in which the pus reaches the abdomen by direct extension. At the present time such cases are less frequently seen than formerly. The catalogue of the Surgeon-General's Library gives one at a glance the literature of empyema about thirty years ago. It is a record of the various

places into which an empyema may extend,—stomach, intestines, esophagus, lung, bronchus.

I want, however, to call particular attention to the extension of the process below the diaphragm into the extra-peritoneal tissues.

Three cases of empyema discharging at the umbilicus have been treated in the Children's Hospital. In one there had been a perforation of the central fibrous portion of the diaphragm between the reflections of the peritoneum above the liver. In two the spread of the pus occurred behind the crura of the diaphragm in the space through which the lymphatics and other structures pass. The pus in either case extends into the retroperitoneal fatty and cellular tissues. It burrows here with great ease, spreading downward into one or both loins, dissecting away the peritoneum from the muscles outside of the semilunar line, until it reaches the lower portion of the rectus muscle, where there is no posterior rectus sheath. The pus then dissects off the peritoneum from the lower part of the rectus muscle until it reaches up to the navel, where it obtains a vent.

Such cases cannot recover until the pleural cavity is properly drained. There is no peritonitis at all in such cases. The process is wholly extra-peritoneal.

The mechanical side of the treatment has been very thoroughly discussed. Two points deserve emphasis,—thorough drainage and complete immediate expansion of the lung. Thorough drainage requires rib resection. When the internist can predict which cases have masses of fibrin in the effusion and which do not, the surgeon may safely consider simple incision in the latter class. But that time has not yet arrived. Rib resection can be done through a very small incision and in a very brief time,—less than two minutes.

Complete expansion of the lung is helped by extremely light anesthesia. The coughing reflex should not be abolished. The fear of a too sudden expansion is, in children at least, a bugaboo.

Chronic empyema is seen in children practically only after an operation which has not resulted in a cure. In such cases, where much and often very foul, pus has accumulated in the chest, it is wise to be content at first to drain off the pus and later to secure expansion of the lung. The danger of septic absorption is minimized.

The prognosis of empyema in children varies greatly with the age. Children over two years old usually recover. In those under a year recovery is a rare exception. In those between one and two years old the outlook is extremely uncertain. Death is not due to any mechanical cause, such as the backing up of pus. It is due usually to the non-resistance to the infection. The infection often shows itself in patches of pneumonic consolidation in different parts of each lung. Death in the young children usually occurs after a few weeks of gradual failure in

the general condition. The power of resistance fails. Fresh air, sunshine, and good food are the only means of help. The aim of sanitarians must be to do away with tenement house conditions if empyema is to be prevented. Physicians must aim in cases of pneumonia to prevent empyema, if possible, by the best hygienic surroundings during the illness.

DR. FRANK L. RICHARDSON, Boston: It seems to me hardly possible that anything more of value can be added. Most of the readers, however, have not mentioned, or have only slightly mentioned, the question of anesthesia. This plays a considerable part in the recovery of patients, especially in the acute cases. It is my personal opinion that acute empyema in adults, where it is possible, should be operated on under local anesthesia. This avoids a certain amount of anesthetic shock and the thing which always follows ether anesthesia, the lessening of phagocytosis. In children, of course, it is not possible to use local anesthesia to such an extent as it is in adults, and here, as Dr. Stone has pointed out, a very slight anesthesia is desirable. It is only necessary to have your patients unconscious to perform your operation. It is not an operation of great delicacy, and if your patient is under lightly you can make him cough at any time, thus expanding the lung and driving out the pus.

In chronic empyema it is an entirely different story. Where decortication is to be performed, I think it is quite essential that intratracheal insufflation should be used, because here you can control the expansion of the lung very easily. This facilitates the work of the surgeon, and facilitates the work of the patient after the operation is over,—that is to say, if you have expanded the lung and filled the pleural cavity there is so much less for the patient to do.

Lung abscess presents an entirely different question. The cases of lung abscess that I have seen do not respond kindly to ether anesthesia. They cough very badly. They cough up sputum which is loaded with bacteria and there is always the chance of their inhaling some of this material and forming new abscesses. This is very much increased where they are under ether anesthesia. Now chloroform, in my hands, in these cases has proved very satisfactory. The chloroform anesthesia does not irritate the lungs as ether does, and patients have little or no coughing.

I want to encroach on the surgical side of lung abscess for a moment. I think this operation should be done in two stages wherever possible,—the first stage to get your pleural adhesions and the second stage for drainage. These two operations under comparatively light anesthesia I am sure do less harm to the patients than one single operation.

DR. WALTER M. BOOTHBY, Boston: Dr. Cotton referred several times to the dangers of "pleural reflex." Deaths occurring during empyema operations have not been uncommon; that they

are due to reflex irritation of the pleural surfaces is, however, by no means proved. He advises freeing and removal of the fibrin by any handy instrument such as a sound, but opposes the use of an irrigation. Why should the sound cause less "reflex" dangers than the salt solution, especially when the cavity has just contained a litre or more of fluid?

Reflexes, if they occur, would in all probability be transmitted through the vagus nerves. Last year, in order to investigate the possible functions of the vagi over the respiratory mechanism,* Dr. V. N. Shamoff (of Petrograd) and I divided on both sides the pulmonary branches of the vagi. This operation necessitated a great deal of handling, cutting and tearing of the pleura, as well as the application of repeated direct mechanical stimuli to the nerves themselves. In none of the animals operated on did we obtain any evidence of "pleural reflexes." In our earlier experiments we had a few sudden deaths on the table due to an improper conduct of the intratracheal anesthesia.

Dr. Whittemore advised the use of intratracheal anesthesia when operating on cases of lung abscess as it would allow the lung to be expanded during the operation. Expansion of the lung is, of course, desirable, if it can be done safely. However, in cases in which the abscess cavity contains an appreciable amount of fluid or is connected with an intrapleural cavity containing fluid, the presence of a tube would be the source of added danger by preventing a free outflow of the pus through the trachea; furthermore, the current of air would tend to blow the pus down into the depths of the opposite lung, with the likelihood of the formation of secondary abscesses. I agree with Dr. F. L. Richardson that under these conditions intratracheal anesthesia would be contra-indicated.

DR. WYMAN WHITTEMORE: In regard to intratracheal ether, which has been said to be dangerous in lung abscess, I believe that it is necessary for the reason that I gave in my paper.

Although ether may be a bad thing to give, yet intratracheal ether I consider a great deal safer than ordinary ether in these cases.

DR. PERCY BROWN: I wish merely to note the spirit of the true internist which has actuated Dr. Sears to speak so modestly concerning the question of the medical diagnosis in these conditions. For my part, I am sure that dependable roentgen diagnosis in pleural cases would have no cause for being if it had not been stimulated by the support of internal medicine.

Dr. Sears's mention of the more routine use of the bronchoscope is an important matter. Systematic bronchoscopy as an especial work would be welcome. Some of our younger men, it is to be hoped, may deem it wise to take this matter up.

* Boothby and Shamoff: A Study of the Late Effect of Division of the Pulmonary Branches of the Vagus Nerve on the Gaseous Metabolism, Gas Exchange and Respiratory Mechanism in Dogs. *Am. Jour. of Physiol.*, Vol. xxxvii, No. 2, pp. 418-431, 1915.

DR. F. B. LUND: I have just one or two things to add. One is that I approve very thoroughly of what Dr. Sears says, that there is no such thing as an "unresolved pneumonia." I do not mean that one should never use the aspirating tube.

Any man who has had experience in these cases will admit that they are often difficult of diagnosis. I think one may willingly admit that the medical men sometimes make the diagnosis before the surgeon does. I recently had referred to me by two medical men a case of double empyema, showing dullness in both backs. The history and temperature looked like double empyema. I tapped in two places without getting pus, and we fell back upon the diagnosis of "unresolved pneumonia," and did not operate. X-rays which were taken did not help us, and the radiologist, Dr. Ellsworth, also thought they pointed to pneumonia rather than empyema. There was no distinct outline to be seen. After five days' waiting, with a temperature running up and down every night and morning, I tapped again on the left and found an encapsulated empyema between the lung and the chest wall high up. The patient's condition not improving, I tapped again on the next day on the left, and by good luck found another encapsulated empyema where I had never found one before,—between the chest wall and the spine. After the drainage of these, she made a good recovery. I simply quote this case as showing the difficulty of diagnosis.

Dr. Homans has spoken of arbitrating between Dr. Cotton and myself. I do not think Dr. Cotton and I are in great disagreement. I have said I believed in trying everything else before resorting to decortication; valves, blow bottles, etc., should be tried. Almost all my patients get well without decortication, but still I am surprised that Dr. Cotton has never had to do it. I have had to do it only three times since I wrote my paper in 1911, and I don't think that shows I am very eager to do the operation. I never attempt it until all milder methods have failed.

Book Reviews.

Diseases of the Nose and Throat. By A. COOLIDGE, M.D. New York: W. B. Saunders Company, 1915.

This book treats in a fairly comprehensive way the subjects of rhinology and laryngology. As stated by the author in his preface, it is not intended in this small volume to give all the information which the student must occasionally seek in books of reference. At the same time

there is a surprisingly large amount of material included in a comparatively small compass.

Certain original features are worthy of special mention: In the chapter on methods of examination, the sections on examination of the trachea by the indirect method and the section on transillumination give valuable points of technic which do not appear in other textbooks. In the next chapter is brought out with emphasis the importance of the clinical history in diagnosis and treatment: a timely warning to over-enthusiastic operators who tend to attribute any and all symptoms of nasal disease to the first anatomical irregularity which they observe. The significance of the cardinal symptoms of nasal obstruction and secretion, hoarseness, cough and obstruction to breathing, is discussed. Under the latter heading is considered the significance of different types of respiratory difficulty. The subject of external fractures of the nose is treated in a particularly lucid way in respect of the mechanics of these injuries, the nature of the displacements and the method of reduction.

In the chapter on diseases of the nasal cavities, the important group of so-called vaso-motor disturbances are given their due prominence.

The author's position in reference to the recently much mooted question of the relation of the tonsils to rheumatism, endocarditis and other remote diseases of infectious origin, is a conservative and sane one. He omits any reference to the part which the sinuses or the teeth may play as foci of infection in these diseases.

Special chapters are devoted to bronchoscopy and esophagoscopy and to disease of the mouth and tongue.

Throughout the book the more common operations are briefly but clearly described. There is a definite avoidance of that profusion of illustrations of operations and instruments which is a characteristic of many textbooks, and which betrays either an author's inability to express himself clearly in language without the aid of pictures, or his desire for an impressive display. There is no lack of illustrations when they are really of value to bring out clearly important points in anatomical or pathological descriptions. There is no padding. The language is clear and incisive. The subjects are taken up in an orderly methodical manner and with a due sense of the proper proportions.

There is a characteristic lack of dogmatic assurance in reference to therapeutic measures for many diseases, which may be disappointing to some who would take up the book in the hope of finding a definite line of treatment recommended as the right one in a given disease. But this lack is manifest only in those instances where definite lines of treatment are not of proved value. Recent advances in methods of diagnosis and treatment are not overlooked. On the whole the author has done well what he set out to do and provided an accurate, useful and interesting textbook.

THE BOSTON

Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, NOVEMBER 25, 1915.

EDITORS.

ROBERT M. GREEN, M.D., Editor-in-Chief.

GEORGE G. SMITH, M.D., Assistant Editor.

WALTER L. BURRAGE, M.D. } For the Massachusetts Medical Society.
FREDERICK T. LORD, M.D. }

COMMITTEE OF CONSULTING EDITORS.

WALTER B. CANNON, M.D.	ALLAN J. MCLAUGHLIN, M.D.
HARVEY CUSHING, M.D.	ROBERT B. OSGOOD, M.D.
DAVID L. ESOLAL, M.D.	MILTON J. ROSENBAUM, M.D.
REID HUNT, M.D.	EDWARD C. STREETER, M.D.
ROGER I. LEE, M.D.	E. W. TAYLOR, M.D.

ADVISORY COMMITTEE.

EDWARD C. STREETER, M.D., Boston, Chairman.
WALTER P. BOWERS, M.D., Clinton.
HOMER GAGE, M.D., Worcester.
JOEL E. GOLDTHWAIT, M.D., Boston.
LYMAN A. JONES, M.D., North Adams.
ROBERT B. OSGOOD, M.D., Boston.
HUGH WILLIAMS, M.D., Boston.
ALFRED WORCESTER, M.D., Waltham.

ERNEST GREGORY, Manager. W. M. LEONARD, Consulting Manager.
SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries belonging to the Postal Union.

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, Manager.

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

THE SYNDROME OF PERIODIC ASTHENIA.

It is well known that many, in fact almost all, of the constitutional psychoses present a certain periodicity as one of their most characteristic traits. This is seen, for example, in periodic psychosis, manic-depressive psychosis, circular insanity, cyclothymia, and psychasthenia. But it is not so well known, or at least generally recognized, that there also exists a clinical entity characterized by period crises of physical fatigue or depression, not accompanied by mental disturbance as a fundamental aspect of the condition, and by no manner of means uncommon clinically. This condition has been properly and instructively described by Déjerine and Gauckler (*La Presse Médicale*, June 17, 1914) under the name of periodic asthenia, which they

describe as a typical and characteristic clinical syndrome.

Minor similar crises of fatigue are normal and perhaps even common in most of us; but as a rule the attacks are so slight, and of such brief duration, that they do not attract our attention in a special or pronounced manner. In some individuals, however, the crises of physical weakness or asthenia, without mental disturbance, are so marked that the slightest exertion produces decided fatigue, accompanied in most individuals by a varying, though generally pronounced, loss of sexual desire. The attacks or crises are characterized by their periodicity, their sudden appearance and as sudden disappearance, all with no apparent or ascertainable cause. Some types are very severe, with very marked general physical asthenia and incapacity, at times with changes in the pulse and arterial tension, disorder of the sebaceous glands and hair follicles, disturbed digestion, frequent attacks of migraine, in some cases loss and in others strange increase in weight, while as a rule the appetite and sleep are good.

The condition occurs as frequently in men as in women, more often in early life, in some instances after a severe attack of typhoid fever, influenza or other infectious disease.

The duration of the individual crisis is one to two days on the average, rarely above a week, although major attacks may last as long as two months or so, and in some cases may continue much longer, almost like an attack of melancholia. The attacks recur two or three times a year or as often as every fortnight. The afflicted individual can find no cause for the condition and so attributes it to the weather or transitory joint changes.

The physician must differentiate this affection from ordinary physiological fatigue, subjective fatigue sometimes occurring in neuropaths, asthenia due to organic disease (as, for example, unrecognized tuberculosis), and asthenia due to definite ductless gland disorder, constitutional neurasthenia so frequent, especially in young persons, inherited or acquired syphilis, and the early stages of general paresis in which attacks of marked asthenia may occur in the initial stage. Not to be forgotten is the appearance of a secondary neurasthenia superimposed upon the original condition here described.

The examining physician, like the patient, can find no particular cause for the condition. But a study of the ductless gland disturbances is of aid

to us here. We know that asthenia may occur in disease of the suprarenal glands, in myxedema and exophthalmic goitre. Pituitary gland has been proved experimentally and therapeutically to stimulate muscle fibres, striated or smooth. Observation seems to show that the glands of internal secretion are so closely interrelated that functional or organic impairment of any one of the chain brings about disturbance in the activity and equilibrium of the others. Furthermore, the periodicity of the functions and disturbances of the ductless glands, especially the thyroid and ovary, is not to be lost sight of. For these reasons, Déjerine and Gauckler are led to believe that the periodic asthenias which they have described are due to a disturbance of the ductless or endocrine gland equilibrium, asthenia alone occurring, or biliary and joint disturbances appearing at the same time.

Therapeutically they declare that the attacks are inhibited or shortened by the administration of thyroid extract (dose 0.10 to 0.15 gm.) with total extract of pituitary gland (dose 0.25 to 0.50 gm.) for three or four days, the dose then being reduced (to 0.05 and 0.02 gm. of thyroid, and 0.10 gm. of pituitary). Complete rest during the period of the crisis, and careful general hygiene in the intervals between the attacks, are indicated.

This syndrome will be at once recognized by every practising physician, for such cases have puzzled us long, and too many of us have permitted ourselves to label the afflicted patient neurasthenic. Whether or not the cause and treatment advocated by Déjerine and Gauckler be found to explain this distressing disorder, the logic certainly is sound, and the authors mentioned have very likely given us the correct solution to this clinical puzzle.

TRACHOMA AMONG NATIVE POPULATION.

SINCE the pointing out by Massachusetts medical men of the prevalence and the dangers of trachoma to the native population through the importation of this disease by immigrants, it was believed the disease was of foreign origin, and that when this source of infection was eradicated the disease would be at an end in

these climes. And, indeed, the barring of immigrants suffering from this condition has awakened not only foreign governments to the menace of this disease, and the taking of measures against it, but the number of immigrants with active disease attempting immigration has fallen to a negligible quantity. On the other hand, because of the treatment received by individuals who desired to emigrate, and who would not otherwise have treated themselves or known of the presence or nature of their disease, the number of cured or completely scarred cases is increasing, until it is now almost a rarity to see an active uncured case of trachoma.

Recently, however, investigations carried out by the Public Health Service of a form of ophthalmia found to be very prevalent among the inhabitants of the mountainous countries of West Virginia and Kentucky revealed the fact that this ophthalmia and the resulting high percentage of blindness was trachomatous, and in nature in no wise different from that previously very heavily imported by immigrants. In some districts the prevalence of this disease was almost universal. If for any reason, or because of the mildness of the few cases found among arriving immigrants, the contagiousness of this disease was questioned, it was again forcibly demonstrated here as it had been when the disease was first introduced into Europe by Napoleon's soldiers from Egypt, under the form of "Egyptian ophthalmia." Indeed, some American observers have evinced a decided leaning towards the notion that this disease was of a non-specific and non-contagious character, and that the overgrowth of the lymphatic tissues of the conjunctiva in trachoma, and the absence of trachomatous disease in the very young in whom this lymphatic tissue is not yet developed, proved that the condition was a mere hypertrophy, of the same kind found in adenoid hypertrophy. It is true that thus far all attempts to locate a specific germ or other specific causative factor have proved fruitless, but then that is true of many diseases about whose contagiousness there is no doubt. To various bacteria found in the discharges have been ascribed the causation of this disease, but thus far none of them has fulfilled the Koch postulate necessitating the isolation, the cultivation in pure culture, the reinfection with the bacteria and the recovery of the specific bacterium. The significance of the oft found negri-like bodies, the so-called "trachom bodies," has not been determined.

Moreover, in these mountain cases whole families were found infected, and the stage of the disease varied only with the age of the individual—that is, the age of the disease. In one family every stage of the disease could be found. The sanitary conditions and the mode of living fully warranted the spread of this disease among them, especially during the winter, when a whole family would be huddled up in one cabin, using the same towel, the same basin, and even the same water.

The trachoma in this native stock could not be traced to present immigrant importation, and the cause must be found among them or be traced further back. This is likewise true of the American Indians, in whom trachoma is so very common,—that the disease may have been introduced among them years ago by foreign settlers.

The communities where this disease was found so prevalent are now, however, alive to the gravity of the situation and are in the course of establishing clinics and constructing hospitals for treating those afflicted. It is to be hoped that the completion of these facilities and the education of the inhabitants in prophylactic measures will eradicate the disease among them, will be another victory in the conservation of vision, and, above all, will be a victory for preventive medicine.

THE ROLE OF INTERNAL SECRETION IN MENTAL CONDITIONS.

SINCE the discovery of the significance of the so-called glands of internal secretion—the thyroid, pituitary and adrenal glands—and of the glands of both internal and external secretion—the ovaries and the testicles—there has been an increase in knowledge of their connections with general metabolism as well as with the functions of the mental and nervous systems. In this respect, perhaps the best known and the most studied, as well as the most amenable to influence, has been the thyroid gland. Here the mental symptoms in secretory deprivation have been particularly marked. They range from the absolute cretinoid idiot to the mildly defective. In certain of the so-called goitrous districts there have been a remarkable number of thyroid affections,

but particularly the cretenoids and the myxedematous. A poor drinking water has been blamed for this condition, but withal not an unsanitary one, for improvements in this regard have failed to affect the conditions. Certain inorganic salts have been believed to be at the bottom of the trouble, but the latest theory is that the poisonous substances, whatever they are, are derived from old marine bodies. However, boiling the water to 80° C. seems to destroy the substances and prevent the development of the conditions. On the other hand, even filtration through a Berkfield filter will have no effect to prevent the condition.

While nothing so definite either as to cause or as to treatment is known about the other gland disorders or diseases, it is yet quite definitely established that removal of the ovaries or testicles, or as to the latter in congenital eunuchoidism, causes a peculiar mentality, characterized often, as in the myxedematons, by a certain slowness of cerebration, apathy, backwardness, peculiar mental and moral characteristics and the like. This is the accompanying mental condition in acromegaly from pituitary disease and in Addison's disease from disease of the adrenals.

It is suggested that if such gross lesions as are found in the conditions just mentioned produce such marked mental symptoms, there may be minor lesions which produce the minor mental conditions, as exemplified by the feeble-minded or the moron. In these instances, for example, the organic lesion, say in the thyroid, is so slight as to be unrecognized with the present methods of diagnosis. Indeed, there have been reported some very good results in the treatment of feeble-mindedness, as well as insanity, with thyroid extract. In all probability, however, at least in so far as the mental conditions are concerned, not one gland alone is at fault. All the glands act in unison, as does every other organization of the system, and the fault may lie simply in a disturbance of the gland reciprocity or association. There need not be destruction or arrest of growth or development, but it may be a disturbance in blood supply, in nervous control, or in the chemical composition of the secretion. But of whatever nature, disturbance of the secretory function causes a destruction and chromatolysis of the nerve cells, and to the extent of the destruction and of the chromatolysis there may be disturbance or deficiency of mental function.

IMPORTANCE OF EARLY USE OF DIPHTHERIA ANTITOXIN.

THE Boston Health Department desires again to call the attention of the medical profession to the great importance and necessity of the early use of antitoxin in all suspected cases of diphtheria. Many deaths from this disease that have been investigated recently show that physicians have depended on the laboratory findings for the diagnosis of this disease rather than on the clinical evidence that has been presented to them.

Antitoxin has been withheld from many cases for so long a period,—viz: sometimes for four or five days,—that death has intervened without the use of antitoxin. Any case that is suspicious enough to warrant the aid of cultural diagnosis should receive at the same time antitoxin treatment. The Health Department is anxious to co-operate with the medical profession in these cases, and will be glad to visit all suspected cases of diphtheria and to furnish aid in diagnosis and, if necessary, administer the antitoxin treatment. Antitoxin has reduced the great mortality of former years from this disease, but during the past few years the deaths from this disease have increased in this city. Many of the deaths from this disease, after investigation, have demonstrated that children have died in some cases without a physician being called, and in others that the administration of antitoxin has been delayed so long that it has been without avail for the cure of the disease.

A case recently investigated, within the past few days, gives a history of a physician being called, case suspicious, and a culture made. Laboratory reported negative. Culture taken the following day was reported to the physician as suspicious and request made for another culture. On the third day another culture was taken, and before a report could be made the child died. This case is but one of many that have recently come to the attention of the department. Early treatment can reduce the mortality of this disease to almost a minimum, and many lives can be saved. However, to achieve this result the Health Department must have the coöperation of the profession. It is earnestly to be desired and expected that such coöperation shall be manifested, since, with the means for absolute control of diphtheria in our possession, it is the responsibility of practising physicians and of the educated public if that control is not effectively applied.

TUBERCULOSIS DISPENSARIES.

IN the monthly bulletin of the Massachusetts Department of Health for October, 1915, is published the paper on tuberculosis dispensaries, read before the recent New England Tuberculosis Conference at Springfield, by Dr. Eugene R. Kelley, director of the division of communicable diseases in the department. In this paper, Dr. Kelley considers successively the measures available in the struggle against tuberculosis, the place of the tuberculosis dispensary in this work, and the essentials of an efficient tuberculosis dispensary. His consideration is based on the application of the Massachusetts dispensary law, whose enforcement has already shown encouraging results. Since July first of this year the tuberculosis dispensaries of the state report a total of 2778 individuals who have had first examinations. Of this total, 27% are examinations made by dispensaries that were non-existent before July. Thirty-two per cent. of the cases are reported from the dispensaries in Boston and the remainder by those elsewhere in the state. Notwithstanding these promising figures, the dispensary system has already shown certain shortcomings, chief of which is a failure of adequate grasp upon the tuberculosis problem and its relation to other phases of public health. Another deficiency is the lack of special training and experience on the part of nurses undertaking this work. Dr. Kelley comments finally on the future problems and possibilities of the tuberculosis dispensary system, which, in spite of its defects, he believes an important factor in the control of tuberculosis. There are, at present, 54 cities and towns in Massachusetts which maintain a tuberculosis dispensary service, and these represent approximately 80% of the population of the state. Complete extension of this system to cover the entire Commonwealth, together with the improvements suggested as a result of its early experience, should make the tuberculosis dispensary system a valuable part of the local struggle against tuberculosis in Massachusetts.

MEDICAL NOTES.

SCARCITY OF MEDICAL SUPPLIES IN CHINA.—It is reported from Peking that the scarcity of medical supplies in China makes it desirable that

there should be established at Shanghai an American firm to supply American hospitals and medical schools in China with the necessary drugs and materials.

"It would seem that the hospitals and medical schools in China experience much difficulty in securing supplies of gauze, cotton of different fibres (sterilizing done in China), suture material, drugs and chemicals in bulk, and surgical instruments. It is recommended that an establishment be opened in Shanghai capable of combining the carrying of stocks of drugs and chemicals with surgical instruments and appliances. There will be a growing demand for these materials in China, especially since the inauguration of the work of the Rockefeller Foundation Commission toward encouraging medical education in this country. The work of this commission will result in securing for certain medical schools and hospitals already in the field a better and more complete equipment and facilities for more extensive work, all of which will involve the creation of a greater market for American drugs, chemicals, surgical instruments and appliances. It is also desirable that the suggested establishment make provision for repairing and nickel-plating surgical instruments, as there is a large and increasing demand for this line of work. The opportunity now presents itself for manufacturers of the United States to see that this general supply house is America."

THE WEEK'S DEATH RATE IN NEW YORK.—

According to Registrar Guilfooy of the Department of Health, 66 lives were saved last week, for had the death rate of the corresponding week of last year prevailed during the past week, 66 more persons would have died. The greatest saving of life was recorded under heart disease, 44 fewer persons dying from this cause during the week just closed than during the week ending November 7, 1914. Noteworthy decreases are also to be noted under deaths from pulmonary tuberculosis and other forms of tuberculosis, digestive diseases and diseases of the nervous system. Both lobar and bronchial pneumonia showed a material increase last week over the corresponding week of last year. Five more deaths were reported from typhoid fever than during the corresponding week of 1914. The total deaths for the week were 1220, with the rate of 10.96 per 1000 of population, as compared with 1236 deaths and a rate of 11.55 for the week ending November 7, 1914. The death rate for the first 45 weeks of 1915 is .40 per 1000 of population lower than the corresponding period of 1914, the rates being respectively 13.13 and 13.53.

PREVALENCE OF MALARIA, MENINGITIS, PELLAGRA, POLIOMYELITIS, SMALLPOX AND TYPHOID FEVER.—The weekly report of the United States Public Health Service of November 5, states that

during the month of September, 1915, there were in Mississippi, 32,532 cases of malaria, 1031 of pellagra, 258 of smallpox and 849 of typhoid fever. During the same period there were in New York State 21 cases of cerebro-spinal meningitis, 49 of poliomyelitis and 833 of typhoid. In Kansas there were 58 cases of smallpox and 229 of typhoid. There were 278 cases of typhoid fever in Indiana.

SOUTHERN MEDICAL ASSOCIATION.—The annual meeting of the Southern Medical Association was held at Dallas, Texas, on November 9, 10, and 11. The principal address was delivered by Dr. Rupert Blue, surgeon-general of the United States Public Health Service, on "Sanitary Preparedness." Dr. Blue emphasized particularly the relation of such preparedness to eugenics.

"The first step in the creation of sanitary preparedness is to teach the citizen the value of a sound body. If, upon the plastic mind of the school child the simple truths of sanitation are impressed, we will gradually create a people in which sanitary living is a habit. If by child hygiene we produce better and stronger men and women, these in turn will have learned that mating with the weak and defective produces weak and defective children. Thus we will have a practical eugenic betterment."

Other addresses were given by Dr. W. L. Rodman, president of the American Medical Association, Dr. Isador Dyer of New Orleans, Dr. Lloyd Thompson of Hot Springs, Ark., Dr. P. N. Whitfield of Florence, Miss., Dr. John L. Davis of Waco, Texas, and Dr. J. Ross Snyder of Birmingham, Ala. Dr. Thompson advocated the legal requirement of a Wassermann test prior to the issuance of any marriage license. As a matter of fact it might seem that the requirement of a Schwartz test would be likely to prevent a larger amount of marital disaster and infelicity.

UNIVERSITY OF PITTSBURG.—At the recent dedication of the Elizabeth Steel Magee Hospital in Pittsburgh, Pa., the University of Pittsburgh conferred the honorary degree of LL.D. on Dr. John W. Williams of Johns Hopkins University, on Dr. Barton Cooke Hirst of the University of Pennsylvania and on Dr. Walter William Chipman of McGill University.

NATIONAL ASSOCIATION FOR THE STUDY OF PELLAGRA.—The third triennial conference of the National Association for the Study of Pellagra was held on October 21 and 22, at Columbia, S. C. At the closing session of the meeting the following officers of the Association were elected for the ensuing year: President, Capt. Joseph F. Siler, M.C., U. S. Army; vice presidents, P. A. Surg. R. M. Grimm, U. S. P. H. S., and Henry W. Rice, Columbia, S. C.; secretary, Dr. James W. Babcock, Columbia, S. C., and treasurer, Dr. James A. Hayne, Columbia, S. C.

UNITED STATES FIRST AID COMMISSION.—In the issue of the JOURNAL for October 28, we commented editorially on the American First Aid Conference held in Washington, D. C., on August 23, and 24, 1915, and on the recommendations and resolutions adopted by that Conference. In accordance with the resolution recommending the appointment of a board on first aid standardization, President Wilson announced on November 9, the appointment of such a commission, whose membership represents seven technical medical and relief organizations. The personnel of this commission is as follows:

Maj. Robert U. Patterson, representing the army and the Red Cross; Surgeon A. M. Fauntleroy, representing the navy; Assistant-Surgeon-General W. C. Rucker; Dr. A. Shelton Horsley of Richmond, Va., representing the American Medical Association; Dr. S. C. Plummer of Chicago, representing the American Association of Railway Surgeons, and Dr. Richard A. Harte of Philadelphia, representing the American Surgical Association. It is believed that the President will later appoint another member so that the army and the Red Cross will each have a representative.

This commission will investigate first aid methods, packages, the standardization of first aid equipment and an identical course of instruction to be followed throughout the country and will report on these subjects to the American First Aid Conference. The president of this conference is Dr. W. C. Gorgas, surgeon-general of the United States Army, and the vice president, Dr. Rupert Blue, surgeon-general of the United States Public Health Service.

LONDON DEATH RATES IN SEPTEMBER.—Statistics recently published show that the total death rate of London for September, 1915, was only 14 per thousand inhabitants living. Among the several districts and burroughs the lowest death rate was 9.4 in Lewisham, a southern suburb, and the highest was 19.9 in Greenwich. This exceptionally high rate in a district which usually has one of the lowest death rates, apparently represents the loss of life from recent Zeppelin air raids.

EUROPEAN WAR NOTES.

CHOLERA IN GERMANY.—During the week ended October 9, 1915, there were in Germany, five cases of Asiatic cholera with one death among the civilian population. A few other cases were reported among prisoners of war.

TRANSFER OF THE WOUNDED ON THE BATTLEFRONT.—A report from a station for the transfer of wounded somewhere in France states that an average of a thousand wounded men have been sent each week into the interior of France for prolonged care. The station has but a single track for the hospital train but the transfer has

been very regular even with a peak load of 1300 patients, 800 of them unable to walk. Every night the beds were full and every noon they were empty. For this station there had been detailed only four physicians and twenty-three aids, but a reserve force was hurried to the spot. At a second centre five consecutive days showed a total of 13,800 wounded, the maximum day being 5520 men.

APPEAL FOR WAR FUNDS.—Report from New York on November 10, states that Mrs. Robert Bacon of that city, chairman of the American committee organized to raise funds for the maintenance of the American Ambulance Hospital at Neuilly, France, has issued an appeal for subscriptions to a fund of \$200,000, which will be needed to keep the hospital in operation for another year. The hospital is at present filled to its capacity of 1000 cases and its motor ambulance service is transporting wounded soldiers from the front to various hospitals to the number of about 10,000 each month. The statement issued by Mrs. Bacon descriptive of the work of the hospital and of its needs is in part as follows:

"Since the service was started it has grown because of the demands made upon it, until we have now three hospitals and about 160 cars in the ambulance section. The base hospital at Neuilly, a suburb of Paris, has now about 600 patients, all serious cases, and the advanced hospitals at Juilly which is maintained by Mrs. Harry Payne Whitney, has more than 200 patients. The third hospital is the portable field tent hospital which consists of thirty-three tents and which was purchased from the Department of War of this country. This is stationed at the front and accommodates more than 100.

"The hospital is in great need of money. It costs about \$1000 a day to maintain the entire service, and we feel quite confident that Americans who have made this work possible will not allow it to suffer from lack of funds."

A further report from New York on November 13, announced the need of contributions to the American War Relief Clearing House for the care of French wounded soldiers during convalescence.

"There are at present in France 170 depots for *éclopés* containing at the present moment 150,000 men, and as the cold weather increases the number will become greater. Some of these men are slightly wounded and some ill, but a great majority of them are those whose nerves have been shattered by the trench warfare. They all must be cared for, and need, in addition to absolute necessities, games for both indoor and outdoor diversion.

"For assistance in caring for these *éclopés* the American Relief Clearing House of Paris has asked for contributions of the following articles: Letter paper and envelopes, lead pencils, needles, buttons, thread, toilet paper, ponchos,

heavy canvas, bed-ticking, sheets, woolen yarn, clothing, blankets, soap in both small and large cakes (should have 6000 pounds per month).

"Contributions of games, such as backgammon, checkers, dominoes, basketballs, footballs, etc., (playing cards cannot be accepted), will do great good in occupying the hands and minds of these sufferers. Cash contributions for emergency relief should be sent to the War Relief Clearing House for France and Her Allies, 15 Broad street, New York city.

"Contributions of material, clothing, bedding, food, games and other supplies should be forwarded prepaid to the warehouse of the War Relief Clearing House, 150 Bank street, New York city, and will be transported from New York to destination in France without expense to contributors."

ST. GEORGE'S FUND.—On November 13, the amount of contributions in Massachusetts to the St. George's fund for the relief of the families of British soldiers and sailors reached a total of \$12,085.54. The principal amounts contributed to this fund in other states are as follows:

New York	\$6066.32
Pennsylvania	5978.53
Connecticut	4289.00
Pacific Coast	4075.68
New Jersey	4062.26
Illinois	3139.89
Michigan	1933.30
Ohio	1467.77
Rhode Island	1272.35

The grand total of the entire fund now amounts to \$47,328.75.

WAR RELIEF FUNDS.—On Nov. 20 the total of the principal New England relief funds for the European War reached the following amounts:

Jewish Fund	\$199,000.00
American Ambulance	69,296.00
Polish Fund	55,446.11
Allied Fund	33,881.30
French Fund	24,048.79
German Fund	16,500.00
LaFayette Fund	12,087.99
Italian Fund	11,835.69
Armenian Fund	10,847.00
Surgical Dressings	9,036.50

BOSTON AND NEW ENGLAND.

THE WEEK'S DEATH RATE IN BOSTON.—During the week ending November 20 there were 203 deaths reported, with a rate of 14.54 per 1000 of population, as compared with 204 and a rate of 14.78 for the corresponding week of last year.

Deaths from pulmonary tuberculosis numbered 16 for the week. An analysis of a group

of recent deaths from tuberculosis gave 18 months as the average duration of illness, though the average length of life after they were reported to the Health Department was only 2 months. This is certainly an indication that some cases are not reported as soon as the diagnosis is made.

There were 40 deaths under 1 year as compared with 35 last year, and 63 deaths over 60 years, against 51 last year.

Total deaths reported in 46 weeks from January 2 to November 20 were 10,411 against 10,423 for the corresponding period last year. Deaths under one year reported in the same period were 1782 against 1775 for the corresponding period last year.

HOSPITAL BEQUEST.—The will of the late Mary T. Gorham of Boston, who died on Oct. 29, contains a bequest of \$2000 to the Cottage Hospital at Exeter, N. H.

BOYLSTON MEDICAL PRIZES.—These prizes, which are open to public competition, are offered for the best dissertation on questions in medical science proposed by the Boylston Medical Committee. They were established in 1804 and are of considerable interest in Harvard University.

At the annual meeting held in Boston in 1913, no prize was awarded.

For 1915, there is offered a prize of three hundred dollars and the Boylston Prize Medal, for the best dissertation on the results of original research in medicine, the subject to be chosen by the writer. Dissertations entered for this prize must be in the hands of the secretary, H. C. Ernst, M.D., Harvard Medical School, Boston, Mass., on or before December 31, 1915.

In awarding these prizes, preference will be given to dissertations which exhibit original work, but if no dissertation is considered worthy of a prize, the award may be withheld. Each dissertation must bear, in place of the author's name, some sentence or device, and must be accompanied by a sealed packet, bearing the same sentence or device, and containing within the author's name and residence. Any claim by which the authorship of a dissertation is made known to the Committee will debar such dissertation from competition. Dissertation must be printed or typewritten, and their pages must be bound in book form. All unsuccessful dissertations are deposited with the secretary, from whom they may be obtained, with the sealed packet unopened, if called for within one year after they have been received.

By order adopted in 1826, the secretary was directed to publish annually the following votes:

1. That the Board does not consider itself as approving the doctrines contained in any of the dissertations to which premiums may be adjudged.
2. That, in case of publication of a successful dissertation, the author be considered as

bound to print the above vote in connection therewith.

The Boylston Medical Committee is appointed by the President and Fellows of Harvard College, and consists of the following physicians: William F. Whitney, M.D., chairman; H. C. Ernst, M.D., secretary; Theobald Smith, M.D.; William T. Porter, M.D.; Henry A. Christian, M.D.; Edward H. Nichols, M.D.; John Warren, M.D.

The address of the secretary of the Boylston Medical Committee is Harold C. Ernst, M.D., Harvard Medical School, Boston, Mass.

BOSTON ASSOCIATION FOR THE RELIEF AND CONTROL OF TUBERCULOSIS.—The annual meeting of this Association will be held at the Twentieth Century Club, Monday, November 29, at 4 p.m. Following the annual reports of the treasurer and secretary, there will be an address by Miss Ella Phillips Crandall, executive secretary, National Public Health Nurses' Association, New York City, whose subject will be "The Tuberculosis Nurse as a Modern Health Agent." She will be followed by Miss Eunice H. Dyke, superintendent of Public Health Nurses, Toronto, Canada. This meeting will be open to the public and should be of interest to physicians and nurses, as well as to tuberculosis workers.

PERSONNEL OF THIRD HARVARD SURGICAL UNIT.—In addition to the members of the third Harvard Surgical Unit, whose names were published in last week's issue of the JOURNAL, the personnel of this unit will contain Dr. William R. Porter of Boston and Dr. C. Franklin MacDonald, a young practising dentist of Brooklyn, N. Y.

APPOINTMENT OF BOSTON SCHOOL PHYSICIANS.—At the meeting of the Boston school committee on November 15, the following board of forty-one school physicians was appointed to replace the former board of eighty members. These appointees will begin their service on November 22 and each will receive an annual salary of \$504, with the exception of one, detailed to the school employment bureau, who will receive \$900. This board will be under the direction of Dr. William H. Devine, who will also have charge of the school nurses. The following is a list of the appointees, who will constitute the personnel of the new board of Boston school physicians:

Dr. Francis G. Barnum, Dr. Joseph A. Cogan, Dr. Simon F. Curran, Dr. Carlisle Reed, Dr. Charles E. Shay, Dr. Frederick W. Stetson, Dr. Edward F. Timmins, Dr. James A. Reilly, Dr. Edward J. O'Brien, Dr. Martin J. English, Dr. Russell F. Sheldon, Dr. William F. Temple, Jr., Dr. Roland W. Brayton, Dr. Joseph B. Lyons, Dr. Bernard W. Pond, Dr. Theodore C. Erb, Dr. George E. Winslow, Dr. David E. Hanlon, Dr. Charles F. Stack, Dr. Irving Sobotky, Dr. John H. Moore, Dr. Phillip E. A. Sheridan,

Dr. Solomon H. Rubin, Dr. Ernest L. Booth, Dr. Harry Olin, Dr. Morris Frank, Dr. Bradford Kent, Dr. James E. Blake, Dr. Edward A. Tracy, Dr. Arnold N. Allen, Dr. Mitchell Sisson, Dr. Joseph H. H. Kelley, Dr. David P. Hayes, Dr. Harry Fein, Dr. William H. Robinson, Dr. Mary T. V. Moore, Dr. Joseph E. Hallisey, Dr. William J. Brown, Dr. Francis J. Doherty, Dr. F. P. Silva, Dr. John T. Sullivan.

Obituary.

GEORGE MILLER STERNBERG, M.D.

DR. GEORGE MILLER STERNBERG, U.S.A., a retired surgeon-general of the army, distinguished both in medical and in military circles, died at his home in Washington, D.C., on November 3, 1915. Dr. Sternberg was born on June 8, 1838, in Oswego County, N. Y., and after obtaining his preparatory education at the Hartwick Seminary, he taught school for three years at Germantown, N. J. In 1857 he began the study of medicine in a physician's office and subsequently attended the College of Physicians and Surgeons in New York, from which he received the degree of M.D. in 1860.

At the outbreak of the Civil War, Dr. Sternberg took the examination for the army medical corps. On May 28, 1861, he was appointed assistant surgeon and was assigned to duty with the third regiment of United States Infantry. He served with this command throughout the war and was successively promoted to be captain and major for faithful and meritorious conduct. At the close of the war he continued in the army medical service and on July 12, 1867, was made lieutenant-colonel for gallant service in the performance of his professional duty in action against the Indians at Clear Water, Idaho. During the next three years he served in various Indian campaigns. In 1871 he was in charge at Fort Columbus in New York Harbor during the yellow fever epidemic of that year and in 1873 and 1875 served in Florida in a similar capacity. During the Spanish War Dr. Sternberg, as surgeon-general of the United States Army, established military hospitals at Key West, and at Fort Thomas, Fort MacPherson, Fort Myer and at San Francisco, and upon his recommendation, two hospital ships were purchased and equipped. The establishment of the Army Medical School at Washington stands also to his credit and is, perhaps, the best known and most important of the services associated with his name. Dr. Sternberg was surgeon-general from 1892 to 1902, and upon his retirement in the latter year was given the rank of brigadier-general.

Miscellany.

HEALTH OF THE UNITED STATES NAVY.

THE annual report of the Surgeon-General of the United States Navy, Dr. Braisted, issued in Washington on November 6, emphasizes on the one hand the increase of tuberculosis and other pulmonary diseases among sailors and, on the other hand, the notable decrease in the incidence of typhoid fever. During the year under consideration, there were in the United States Navy 38 deaths from tuberculosis and 33 from pneumonia. The reason for this exceptional incidence of pulmonary disease is attributed "to the crowded condition necessary to manning and equipping vessels of war, in which hygienic primal principles, such as are accepted as indispensable in life on shore, practically never achieve recognition.

"Overcrowding, extreme reduction of the amount of air space per person, improper proportion of moisture and the inappropriate placing of air inlets and exits, over- or under-heating of the air,—these are all faults and problems incident to the packing of 1000 men in quarters which theoretically should hold but 300."

With typhoid fever, however, the situation is the reverse, since the adoption of compulsory anti-typhoid inoculation. Three years ago there were in the Navy, 222 cases of typhoid fever with fifteen deaths; last year there were only 15 cases and no deaths. Dr. Braisted believes that this practical elimination of typhoid fever from the navy is due almost entirely to prophylactic inoculation.

"While the reduction in morbidity has been coincident with a marked improvement along the same lines in the civil population of the larger cities of the United States, which cannot be ascribed to immunizing methods, the improvement in our service has far outpaced that ashore. Undoubtedly the country-wide education regarding sanitary principles, as disposal of waste, improvement of water supply, more extensive pasteurization of milk, anti-fly campaigns, etc., have been most potent in producing the results, shown in tables, taken from the *Journal of the American Medical Association*.

"Reports from the armies of the contending nations now in the field show remarkable improvement. The Germans, who had provided extensive hospital accommodations for expected or possible incidence of typhoid, measured by standards of previous conflicts, have been able to convert these facilities to other uses owing to the comparatively slight incidence of what was once the worst scourge of a military campaign. In the British Expeditionary Force in France during the first ten months of the war the ratio of morbidity was 14 times, and of mortality

forty-two times greater among the uninoculated than among the inoculated. (*British Medical Journal*.) The sanitary condition of the French Army is particularly satisfactory. No epidemics have appeared, thanks to the knowledge and strict application of the fixed laws of hygiene. If a few isolated cases of typhoid fever appear, it is because those who are attacked have not been protected by vaccination, or have been vaccinated in an unsatisfactory manner as to quantity or method of application. In the early months of the war, moreover, since preventive vaccination had not yet been made general, and numerous cases were presenting themselves in the infectious hospitals, it was thought that cases of typhoid fever had been found in those who had been vaccinated. This was not so. These cases have been found to be paratyphoid. (*Lancet*, London, Aug. 7, 1915.)"

In conclusion the report recommends the provision of two new hospital ships in addition to the *Solace*, the only hospital ship now in the Navy. It further recommends that arrangements be made for the purchase of additional merchant craft for use as ambulance ships or medical transports in time of war.

MILITARY MEDICINE IN THE SEVENTEENTH CENTURY.

In the issue of the *Lancet* for October 16, 1915, appears an editorial comment on two seventeenth century books of military medicine and surgery which have recently been acquired by the library of the Royal Society of Medicine. Both these works were printed in London by William Goddard and were "sold by one Moses Pitt at the Angel over against the little north door of St. Paul's Church." The first book is entitled "Cista Militaris or a Military Chest," being a description of "Dr. Lower's lancet for the more safe bleeding with an illustration thereof."

"The chest was based on the 'Military Chest of the most Illustrious Heroe, Maurice, Prince of Orange, wherein not onely Medicines and Instruments, but also Linnen, Rowlers, and other Necessaries were prepared.' Of the medicines, a supply was to be kept of Purging Simples, Purg-ing Compounds, Electuaries and Powders Strengthening the Heart and noble parts, Aromaticks, Distill'd Waters and the like, Syrup, Roots, Herbs, Flowers, Seeds, Fruits, Oyl, Unguents, Fats, Plaisters, Gums, Minerals and Meals. The Chirurgion is also to be furnished with necessary Instruments some to be fitted for a Box to carry about him in his Pocket; these ought to be made small and little, that they may neither load him, nor affright the Patient. Among these figure Trepanns, Levatories, Sealpra's, Instruments to draw forth Bullets from Gunshot Wounds, and a great Saw for amputating Great Members. We learn further that a Chirurgion

ought to be provided with splints of several big-nesses, made of thin pieces of wood. Finally, Lint to keep the lips of the Wounds asunder, that they unite not again. And to conclude: Candid Reader, be sure that it be so provided with mendicaments and Instruments, that out of it, when occasion requires, thou mayst be able to assist and relieve the Sick; for what thou art employed about here, is neither Beast, nor Pretious Stones, but Man for whom the Son of God shed his pretious blood upon the Cross.

"The second book is entitled 'A Body of Military Medicines Experimented by Raymundus Mindererus, late Chief Physitian of the Electoral Court of Bavaria, and Englished out of High Dutch.' It begins with the Morals of a Souldier, who ought to serve his Prince faithfully to the best of his skill and power, to obey his Officers readily, and to do to all others, as he would be done to, if he were in their condition. Then is given advice regarding the care of his Body as follows:—To free thyself from Vermin, take a good quantity of Wormwood, and the inner cuttings of horse-hoofs; boyl these both together in half lye and half water, and so put thy shirt into it, and afterwards dry it in the Air, without washing it out any other way, and not a lowse will come into it. If thou canst not have Spring water, let some drops of Oyl of Vitriol fall into it, and you need not then fear any corruption or poyson in such water. Otherwise if time will permit, let it boil up and cool again, and you may drink of it safely. Concerning the Army Medical Staff we learn:—These ought to be no Youngsters, that are lately come from Schools and Universities, but such as are expert in the Cure of Diseases. The Physitians and Chirurgions are to be intimate friends together, assisting one another without envy and pride, for the better relief of their Patients. 'Tis very necessary, both these should go abroad and travel before they undertake to practise, thereby to learn to converse with the more discretion and gentleness with all sorts of humors. In therapeutics the work is both informing and dogmatic:—To avoid fevers, keep thy body clean every way; be chearful; never fasting, nor never full. To heal injuries, keep the wound clean, and let not many look into it, for fear they should by their breath annoy it. You may also recover frozen Feet with white rotten Turnips, beaten with Butter or Tallow, and so clapt on. If you have a strong breath, take now and then three or four Aloes-pills."

SEIZURE OF SUBSTITUTE SPECIFICS.

THE United States Department of Agriculture has recently issued the following statement relative to its seizure of certain cheap imitations of well-known preparations which have recently been put on the market during the

shortage of certain drugs on account of the European War. Reference to these fraudulent drug substitutes was made in a recent issue of the JOURNAL.

"Several shipments of worthless imitation drug products have been seized by the officials in charge of the enforcement of the Food and Drugs Act. Itinerant peddlers are selling to drug stores large quantities of preparations made up and labeled in imitation of high-priced patent medicines of foreign origin. Only small quantities of the genuine medicines have been imported since the war began, causing a great increase in prices. Unscrupulous manufacturers are attempting to reap a harvest by substituting for the genuine medicines cheap chemicals with no medicinal value whatever. In order to make it difficult to trace these preparations to the parties responsible for their manufacture, they are not usually distributed through the regular channels of commerce, but are peddled about to drug stores by itinerants, who make immediate delivery at the time of sale.

"A preparation put up in imitation of "Neosalvarsan," a medicine which has largely displaced the preparation known as 606 in the treatment of syphilis, is being distributed to drug stores in this manner. A sample labeled "Neosalvarsan," which was recently examined by the Department, was found to be nothing more than salt colored with a coal tar dye, none of the genuine neosalvarsan whatever being present. The label on this product was an exact reproduction of the genuine imported neosalvarsan, or it was an original container refilled with the imitation article.

"This fraud is held to be particularly flagrant, according to the medical experts of the Department, not alone because a worthless preparation is sold for a high price, but mainly because neosalvarsan is usually administered by injection directly into the blood of the syphilitic patient. The cheap substitute is not only worthless in the treatment of this disease, but when injected directly into the blood might work considerable injury.

"Other preparations which are peddled to druggists and purport to be acetylsalicylic acid, commonly known as aspirin, a medicine of foreign origin regularly prescribed by many physicians for certain ailments, have been seized by the officials in charge of the enforcement of the Foods and Drugs Act, because an analysis showed that the products were worthless imitations.

"Owing to the manner in which these preparations are peddled about, it is difficult to trace the interstate shipment of any of them, and in cases where there has been no interstate shipment the Federal Food and Drugs Act has no jurisdiction. On information furnished by the Federal authorities some of these imitation goods have been seized by city officials who had authority under state laws to proceed when there had been no interstate shipment."

Correspondence.

MEDICAL EXPERIENCES OF A RHODES' SCHOLAR IN THE EUROPEAN WAR.

(From Our Special Correspondent.)

DEPARTMENT OF PATHOLOGY,

UNIVERSITY OF OXFORD, OCT. 26, 1915.

Mr. Editor: During the course of this war, I have had opportunities of seeing and of working in some of the war hospitals in England, France and Serbia, as well as in Germany. In Serbia where I worked during the typhus epidemic, hospitals consisted of schools, barracks, factories or any buildings that happened to be larger than the ordinary small Serbian mud cottages. The equipment was most primitive. Beds were simple sacks of straw upon the floor. If the hospital was not overcrowded each patient had a sack to himself, but during the height of the epidemic two of these rude mattresses had to be placed together, to be shared by three men. The bed clothing in a good hospital consisted merely of a blanket, but in ordinary places a patient was compelled to keep warm as best he could, with the remnants of his uniform and overcoat. Food, consisting of soup and bread, was usually sent to the different hospitals in each town, from one central kitchen, and at meal times you would see pairs of Austrian orderlies, for the prisoners did all of the rough work, marching through the market place with a huge cauldron of soup suspended from a pole on their shoulders. For medical treatment they were reduced to more or less futile attempts at cleanliness and fresh air, the former being difficult because of the vermin, and the latter was opposed by the Serbs on general principles. In fact the only way windows could be kept open while one's back was turned, was to break the glass. As a rule, drugs were reduced to aspirin to treat the headaches which are so terrific in typhus. Very little beyond this could be done because of the lack of supplies. The routine on admitting a patient was to remove his clothing to be sterilized if possible, to give him a bath, to clip his hair and if any ether was available, to scrub his head with it, for if this precaution was not taken, your patient would be literally alive with lice again within a few days, for the eggs remaining in the roots of his hair would have hatched.

The real need of Serbia during the epidemic, however, was not hospitals to care for the victims, after typhus had already set in, but sanitary organization to prevent and limit the spread of the disease. The overcrowding of the center of the country by refugees from the northern districts, invaded by the Austrians, had produced such filth and bad living conditions that the typhus had every opportunity to increase and flourish. This sanitary organization has now been accomplished by the American Red Cross Sanitary Commission in spite of the great difficulties caused by the ignorance of the general population. But now that Serbia is suffering from a second invasion that is many times worse than the early one, and the population is fleeing in hordes toward the Montenegrin frontier and overcrowding the villages in that region, it is difficult to imagine what will prevent a repetition of last winter's scourge.

From Serbia I went to Italy with Sir Thomas Lip-ton, who was using his yacht *Erin* for Red Cross transportation, and from Italy I reached England by crossing Austria, Germany and Holland. Although the towns in Austria which I visited were filled with wounded, yet it was not until I reached Germany that I had opportunities of going through war hospitals. The first one that I visited was the German-American hospital in Munich. The contrast of their equipment and efficiency with the poverty and incompleteness of Serbian hospitals was amazing to

say the least. Everything was completely organized and systematized. When the head surgeon made his rounds every man who could move, even an unfortunate man with one leg, came to attention at the foot of his bed. This strict discipline in the hospitals was very noticeable, and the fact that cures seemed to require less time there, than in English or French hospitals where patients are allowed more freedom, might justify it. The war has reduced the medical supplies of Germany to such an extent that cloth bandages and dressings, and all preparations requiring glycerine were rigorously conserved. The Germans carry their dislike of England and the English language so far, that I saw an American nurse severely reprimanded by her chief, for writing notes on her medical chart in English instead of in German. But the thing that impressed me most was that the German authorities were not merely content with curing their patients as quickly as possible, but that in addition they laid great stress on putting a patient into such condition, that when discharged, even though unfit for military service, yet he could still be self-supporting and not be a burden upon the state. "There must be no unnecessary cripples at the end of the war" was the text of the official order from Berlin. Therefore, every bone wound had to be treated by an orthopedic surgeon. Of course, this involved tremendous work on the part of the whole medical service, but the splendid results which I saw at the Orthopädische Klinik certainly vindicated the extra labor, for Germany will have a smaller proportion of cripples than the other nations after this struggle is finished. After a man is passed as medically fit for military service again, he is granted a furlough before he is sent back to the trenches and, I believe, that the Germans are less reluctant to go back than the men of the Allies, although this may be explained by the feeling of obedience to discipline that is well drilled into a German soldier.

In France, where I worked for two months before the Serbian epidemic, the hospitals were all well equipped, and with the exception of the first few months when the wounded transportation system had still to be properly organized, the medical service was most efficient. At the American Ambulance at Neuilly, for instance, motor cars were kept constantly at La Chapelle where the Red Cross trains arrived. Patients were quickly brought to the hospital and inspected at once by the medical officer of the day. The patient is then undressed, all of his clothing and kit are sent to the sterilizing department and the man is given a thorough bath before being carried to the ward. Practically all of the men are given anti-tetanic serum at the first dressing station and the letter A is then chalked on the left leg, but if the stress has been too great, as during the engagement at Soissons, this injection must be omitted until later, so that one of the first duties of the receiving medical officer is to look for this chalk mark. If it has not been made, or in many cases, if it has been rubbed off during the transportation from the front, anti-tetanic serum is immediately administered. Consequently tetanus is practically wiped out. Although at present the hospital discipline has become more rigorous, yet the French *piou-piou* is much happier and more contented to remain wounded than the German Fritz.

In the English hospitals not only those conducted by the Royal Army Medical Corps but also in the American Women's War Hospital at Paignton, and in the Canadian Red Cross Hospital at Clevedon, one finds that the German efficiency is combined with a more human interest in the patient and his happiness. Tommy may not be put back into action quite as quickly as a German soldier but he certainly has much more comfort and pleasure during his stay in a base hospital. The medical transportation department has been splendid. Men from France are quickly passed through dressing stations and if the wounds are not too serious, they are sent home to England. From the Dardanelles small boats transport the wounded from the dressing stations on the shore of

Suvla Bay on Cape Hellas to hospital ships lying off shore, and if they happen to return by the *Acquitania*, they reach a base hospital in England within six days, while even the slowest ships always make the voyage in ten days. This sea trip has a very beneficial effect on the patients and very many of them are practically convalescent when they reach England.

A very large proportion of the cases from the *Pardanelles* have been medical—dysentery, both amebic and bacillary, paratyphoids, and a few rare cases of typhoid, although the "typhoid" inoculation has practically stamped out the last named disease.

In the care of wounds England has made tremendous contributions to science. For instance, I have seen what appeared to be hopelessly infected shrapnel and bullet wounds quickly cleaned up, and the patients' temperatures brought back to normal by immobilization and constant surface drip irrigations with hypertonic salt solutions. The treatment of fractures has also been greatly improved, and since the exhibition of new splint shield in London last week many new ideas have been put into practice. One patient in our base hospital here in Oxford with a compound fracture of the femur who required two orderlies to move him into a position so that his wounds could be dressed can now, with the aid of a new splint which suspends his leg on a movable trolley overhead, move himself about on his bed with perfect ease and no pain.

Very truly yours,
WILBERT C. DAVISON.

EXAMINATION OF NOSE IN EYE DISEASES.

HOTEL HARVARD, 640 HUNTINGTON AVE.
ROXBURY, MASSACHUSETTS.

Mr. Editor: When I was treating eyes at the Boston Dispensary, my friend Dr. E. U. Spear called my attention to the fact that many diseases of the eye,—conjunctivitis, blepharitis, episcleritis,—are dependent upon diseases of the nose. It is certain that they will not get well unless the nose is treated. Of course no competent oculist would operate for cataract unless he had made the tear passage sterile. I urge upon all eye surgeons to examine the nose in every eye case of an inflammatory nature, or to have it done.

Your obedient servant,

EDWARD L. PARKS, M.D.

SOCIETY NOTICES.

NEW ENGLAND PEDIATRIC SOCIETY.—The thirty-ninth meeting of the New England Pediatric Society will be held in the Boston Medical Library, Friday, Dec. 10, 1915, at 8.15 P.M.

I. Report of Council and nomination of officers.

II. Report of Treasurer.

III. The following papers will be read:

1. Simple Incision in the Treatment of Pyloric Stenosis, by James S. Stone, M.D., Boston.

2. Spasmodic: Report of Ten Cases.—Etiology and Treatment, by Fred P. Webster, M.D., Portland, Me.

3. Fermentative Diarrhea in Infants, by Lewis W. Hill, M.D., Boston.

IV. Election of officers.

Light refreshments will be served after the meeting.

F. M. BUCKINGHAM, M.D., *President*,
RICHARD M. SMITH, M.D., *Secretary*.

Discussion by David N. Blakely, M.D., M. J. Cronin, M.D., Edward N. Libby, M.D. Refreshments after the meeting. Telephone Roxbury 22753.

BRADFORD KENT, M.D., *Secretary*,
798 Blue Hill Ave., Dorchester.

THE HARVEY SOCIETY.—The third lecture of the series will be given at the New York Academy of Medicine, 17 West 43d Street, on Saturday evening, Nov. 27, 1915 at 8.30 P.M., by Dr. Eugene F. Du Bois, Cornell University. Subject: "The Respiration Calorimeter in Clinical Medicine."

RECENT DEATHS.

DR. HORACE CHASE, a Fellow of the Massachusetts Medical Society since 1867, died at Dorchester (Boston), Mass., January 11, 1915, aged 83 years.

DR. CHARLES A. CHURCH, who died recently at Passaic, N. J., was born at Norwich, N. Y., in 1840. After receiving his preparatory education at Norwich Academy, he attended the Hahnemann Medical College of Philadelphia, and the New York Homeopathic Medical College. He was a member of the staff of the Passaic General Hospital and of St. Mary's Hospital at Passaic. He was formerly president of the New Jersey State Homeopathic Medical Society and of the New Jersey Medical Club. He is survived by his widow and one son, also a physician.

DR. WAYNE SMITH, who died of cerebral hemorrhage at Detroit, Mich., on November 12, was born in 1876. He was formerly for several years superintendent of the St. Louis City Hospital, and was known as an expert on hospital administration, concerning which he had published several works. He came to Detroit in 1913 as superintendent of the Harper Hospital in that city, a position which he held at the time of his death.

DR. EDWARD LIVINGSTONE TRUDEAU, who died on November 15 at Saranac Lake, N. Y., was born in 1848. He received the degree of M.D. from the New York College of Physicians and Surgeons in 1871 and, at first, began the practice of his profession in New York City. In 1884, however, he established a sanatorium for the treatment of tuberculosis at Saranac Lake; and from his work at that institution became noted throughout the country as an expert in the knowledge and treatment of the disease.

DR. ALBERT VEEDER, who died on November 16, at Lyons, N. Y., was born at Ashtabula, Ohio, on November 10, 1848. After graduating from Union College, New York, he received the degree of M.D. from the University of Buffalo, and after teaching for a time, engaged actively in the practice of his profession at Antwerp, N. Y. He had been interested, also, in experimental work on the transmission of typhoid, the open-air treatment of pulmonary tuberculosis, the problems of public water supply, garbage disposal and other aspects of sanitation.

DR. JOHN C. WEBSTER, who died on November 15 in Chicago, was born at Hopkinton, Mass., in 1843. He received the degree of A.B. from Dartmouth College in 1864 and that of M.D. in 1867 from the Harvard Medical School. He immediately settled in the practice of his profession at Chicago, in which he remained actively engaged until his retirement in 1908. He is survived by his widow and by four children.

APPOINTMENT.

WASHINGTON UNIVERSITY MEDICAL SCHOOL.—Dr. Leo Loch has been appointed professor of comparative pathology.

THE NORFOLK DISTRICT MEDICAL SOCIETY.—A regular meeting of the Society will be held at Masonic Temple, 171 Warren Street, Roxbury, Tuesday, Nov. 30, at 8 P.M., sharp. Business communication on chronic nephritis by David L. Edsall, M.D., and dis-

Address.

THE DANGERS OF ETHER AS AN ANESTHETIC.*

By W. W. KEEN, M.D., LL.D., PHILADELPHIA.

Emeritus Professor of Surgery, Jefferson Medical College.

It is a great pleasure to tender my thanks to the Trustees and the Committee for their kind invitation to deliver an Ether Day Address.

In this historic place, 69 years ago this very day, occurred the first public use of ether as an anesthetic. We, who are accustomed to anesthesia, can hardly appreciate the courage of Warren and Morton on that memorable sixteenth of October, 1846. Surely also the bravery of the patient himself should not be overlooked. The name of Gilbert Abbott should always be held in remembrance.

I have often called the attention of my classes to a patient lying limp and apparently almost lifeless on the operating table. Lift the arm and it falls as if it were that of a corpse, touch the sensitive eye and the lids do not move. Cut the tender skin and it elicits no response. "Will he ever wake up?" "May not the flickering flame of life gradually fade away and forever?" "Have I not unwittingly killed this man?" Such must have been the insistent questions in

the minds of those intrepid adventurers on that momentous occasion. How eagerly must they have welcomed the first faint evidences of returning consciousness! Had that young man died then and there, for how many years would the blessings of anesthesia have been withheld from the human race? Only eleven years earlier (1835) Père Velpeau, the great French surgeon, had said, "Eviter la douleur dans les opérations est un chimère qu'il n'est pas permis de poursuivre aujourd'hui." Who would have dared to repeat the dangerous experiment? For an experiment and a most hazardous experiment on a human being, it certainly was. Happily the result justified their temerity and millions have been blessed by the bravery of the surgeon, the anesthetist, and the patient.

In Berlin where I was a student in 1865-6 the story ran—and I believe it was authentic—that a short time earlier Henry B. Sands of New York, urging the greater safety of ether upon Langenbeck, at his request, gave ether for him in his clinic. The patient died on the table from the anesthetic. Naturally this deferred the use of ether in Germany for years and cost many lives.

In this city and this hospital my topic—The Dangers of Ether as an Anesthetic—may at the first blush seem ungracious. But our profession ever seeks the unvarnished and unvarnished truth. To recognize that there are dangers is the first step in eliminating them. When life is at stake ignorance is not bliss. Forewarned is forearmed.

* Address delivered at the Massachusetts General Hospital, on the sixty-ninth anniversary of Ether Day, October 16, 1915.

When I accepted the invitation and selected my topic, which had not been considered in any of the former Ether Day Addresses, I thought I had chosen an easy task. But I had hardly begun my work when I found that great progress had been made, as to much of which I was inadequately informed.

While I have had a large experience during a long and active surgical life, yet, in consequence of my retirement from active practice in 1907, I have had little or no personal experience with a number of the newest anesthetics and the latest modes of their administration. Accordingly, to make up for this lack, I devoted the past summer to the diligent study of the recent work on anesthetics and anesthesia by reading the extensive literature (especially the valuable physiological literature) of the last ten years, to a considerable correspondence, as the friends whom I persecuted will testify, and in the early autumn to some careful observations of the administration of anesthetics in Boston, New York, and Philadelphia. It has had all the fascination of novelty and the exhilaration of success.

When I began my medical studies in 1860 there were but two anesthetics in use, ether and chloroform. Now the many anesthetic drugs, the different methods of using them, by inhalation, by insufflation, by arterial or venous infusion, by different routes,—the mouth, the nose, the rectum, the colon—by local anesthesia, by spinal anesthesia, by one drug alone or by two or more, together, or in varying sequences, by simple or complicated apparatuses, or costly and elaborate chambers for differential pressure, have almost reached the classical "57 varieties."

During the last 10 years especially, the administration of anesthetics has been rapidly changing. It is becoming more and more an exact science instead of a mass of only empirical knowledge gained by practice and at the cost of danger or sometimes even of life. The multiplicity of valuable papers, the many set discussions in our medical societies, the exhaustive studies in our laboratories of research on the physics, the physiology and the chemistry of respiration and of anesthetics, the pathological changes observed in animals after intentional or accidental deaths, and after similar accidental deaths in human beings, the accumulated large statistics all demonstrate the deep interest, the scientific activity and the happy results of this new outburst of work in anesthesia.

One of the happiest results of this restless search for improvement is the rise of the *professional anesthetist*, an expert who by his mastery of the subject and his knowledge and presence of danger, is able to avert or to remedy the danger—an expert who is more and more definitely coming to be recognized as comparable to the expert specialist in other departments of medicine and surgery. Says Bloodgood,¹ "Accumulated experience and reading

... impress me more and more that anesthesia is an art in every sense of the word. *Specially trained anesthetists are necessary for safety.*"

The recent organization of the American Association of Anesthetists is another welcome evidence of progress. That professional specialists in anesthesia are greatly needed is strikingly shown by the frank reply to my questionnaire by the chief anesthetist of one of our best American hospitals. "To what do you attribute the deaths from ether?" was my question, and his reply began "Lack of skill in its administration."

That such experts are specially needed in America is shown by the fact that Gwathmey's American statistics² compared with those of Hewitt in England show that in this country our percentage of mortality from ether is *over three times as great as in Great Britain*.

Let the general public who may read this may take alarm and exaggerate the dangers of ether, let me say at once that the deaths are estimated in various statistics as being only one death in 4533 administrations in America (Gwathmey), one in 5112 in Germany,³ one in 16,302 in Great Britain,⁴ and even only one in 50,000 (Rovsing).⁵ But even if it be only one in 50,000 yet if that one is *your* boy, it is a sorry consolation to know that 49,999 others escaped.

As soon as I fixed upon my topic I sent out to the members of the American Surgical Association a questionnaire as to immediate and delayed ether deaths, requesting exact figures if they were available, and estimated figures if they were not. I received 67 replies, for which I tender my sincere thanks to my correspondents, a number of whom took much pains in compiling their statistics.

In 20 replies the figures were exact, though those of several active surgeons covered only a very few years. These returns showed,

Exact number of etherizations262,002
Number of deaths34
Or 1 death in	7,706 cases.

This is an improvement over Gwathmey's statistics, but the 34 deaths do not include some delayed deaths from pneumonia, nephritis, etc., which would probably bring the proportion down to about Gwathmey's figures or possibly worse. The 47 others—including, I regret to say, myself—could only estimate the number of their cases and deaths. The approximation to former statistics is gratifying as showing that the estimates were reasonably accurate and not too seriously optimistic.

Estimated number of etherizations	356,500
Estimated number of deaths73
Or 1 death in	4,884 cases.

Both the estimated and the exact numbers show that we have still over three times the relative number of deaths as in Great Britain—a

serious blot on our methods and results. This calls loudly for reform. The systematic use of duplicate charts, if collected from all available sources at intervals of five years, would show whether our results were improving or growing worse.

Compared with chloroform the dangers of ether are almost negligible. In Great Britain from 1910 to 1913 there were 700 inquests on deaths from anesthetics.⁶ Of these, chloroform and its mixtures were responsible for 478 and ether for only 28. What is the relative *percentage* of fatalities of each, however, we do not know.

Personally I was brought up by the elder Gross in the Chloroform School, and I generally used it in my earlier cases. But I was soon convinced of my error, and for the last forty years I have used chloroform very, very rarely. I regard it either alone or in mixtures as a most dangerous anesthetic. With Bevan⁷ and the Committee on Anesthesia of the American Medical Association,⁸ I would urge that it should be discarded, excepting in a few special cases, also in the tropics and in military surgery on or near the battlefield, and on naval vessels during action.⁹ In base hospitals and on hospital ships ether should be used.*

What we want is such an anesthetic and such anesthetists that there shall be *no deaths at all*. The search for this ideal anesthetic must be vigorously continued by experiment first upon animals. It has not yet been found, for every anesthetic known has its own dangers. I fear that even the best future anesthetic may not be wholly free from this possibility. As I have more than once pointed out, the ideal anesthetic should not preserve the consciousness of the patient, who would easily be terribly frightened at the least suspicion of danger, dangers which the surgeon has often encountered and easily vanquished. They would not only alarm the patient, but would often provoke uncontrollable physical movements which would cause serious dangers or entirely prevent the operation. This ideal anesthetic must also, if possible, be pleasant to administer, efficacious in abolishing all pain, free from noxious after-effects, and, if possible, without danger to life.

Our commonest anesthetic—ether—is to me, personally, both as surgeon and as patient, so little repulsive, and has such very slight danger in competent hands, that after having used it thousands of times with patients, and taken it myself on six different occasions, so far as any feeling of apprehension or repugnance is concerned, I would as lief lie down on the table and take ether as I would sit down at my table and eat my breakfast. No

* The papers and discussions on Anesthesia in the American Surgical Association in 1912 and 1915 will well repay perusal by every surgeon and every anesthetist.

one, however, except by *force majeure* shall ever again give it to me as on the first occasion, in 1863, from a closed cone saturated with ether, which almost suffocated me. By the open drop on a mask or the Allis inhaler,* which are practically equivalent, I have five other times been most pleasantly and efficaciously anesthetized. Not once have I had the least nausea. The long-continued ether taste and once some gas pains were the only unpleasant aftermaths. *Haud ineptus loquor*.

"If patients could be educated to be as pleased when they are told that a surgical operation is necessary as they are when given a tonic, Utopia would be reached," says Bloodgood.

I reached such a Utopia some years ago when a young girl burst into tears upon my telling her that an operation for appendicitis was necessary. I tried to comfort her, but to my surprise she replied between her sobs that she was weeping for joy, for she had feared I would decide *not* to operate. Such Utopias, however, are not yet common, but I have found them gradually growing more frequent as the public are more and more convinced of the safety of modern operations and the danger of delay.

The students in our medical schools see a great many anesthetized patients, but their attention is given chiefly to the operation. Too often they receive little and in some schools no careful instruction in anesthesia. Far too frequently the function of the etherizer is delegated to the ever-changing junior residents, as if, forsooth, it were of minor importance. Next to the surgeon and even before his first operative assistant, in my opinion, stands the anesthetist, holding the scales of Life and Death. Happily, at least in the use of ether, the margin of safety is so wide that even inexperience and inattention are rarely harmful.

It should be the duty of our medical schools and their hospitals to *instruct all students in anesthesia and to give them experience* by having them administer anesthetics under the supervision of their experts. In view of the constant and necessary change of internes there should be on the staff of each division a permanent expert. In small hospitals at least one of the staff should make it his business to become an expert by constant study and practice.

The anesthetist should if possible always see the patient beforehand. He can thus establish an "*entente cordiale*" which will do much to prevent fear and other psychic elements of danger.

Gerster says that long ago he learned in Billroth's clinic to be careful with patients who exhibited fear but that he never understood the reasons until Crile and Yandell Henderson explained them.

The most striking instance of the *physical results of fear* I have ever known personally was a

* The ether should be dropped on the Allis inhaler just as on a mask, slowly at first, faster and faster in a few minutes, but never poured in. Moderate rebreathing can be obtained by covering the upper surface by the hand.

little girl of nine in my ward at the Jefferson Hospital. Her clothing had caught fire and she had been so dreadfully burned that a year after the accident I was compelled to amputate the left arm at the shoulder joint. She made an excellent recovery *per primam*, but had not been discharged because an old ulcer on the deltoid flap had not yet quite healed. Four weeks after the amputation she was suddenly awakened in the middle of the night by a nearby fire. The ward was high studded, the windows many. It was no wonder, therefore, that remembering her own dreadful experience and seeing the flames and the brightly illuminated ward, she should think the ward itself afire and become terrified. A thoughtful nurse took her temperature, which had long been normal, and found it 105.4°. The next morning it was 99°.

A similar but less striking instance is recorded by Crile and Lower¹⁰ in which simple fear raised the temperature to 101.2° and the pulse to 150. Bloodgood¹¹ reports a case in which fear alone caused the blood pressure to fall in ten minutes from 140 to 80 m.m. In some cases even death has resulted from fear before an anesthetic has been given.

Crile is none too insistent upon the psychic as well as the physical conditions, which are so conducive to smooth recovery.

The condition of the blood should be ascertained beforehand in all serious operations, especially in anemic patients. DaCosta¹² and DaCosta and Kalteyer¹³ and others have demonstrated the diminution of hemoglobin due to ether. While Mikuliez advised against any general anesthetic in case the hemoglobin was below 30%, DaCosta and Kalteyer represent a better present opinion by drawing the line at 50%.

Observation and charting of the blood pressure not only beforehand, but at frequent and regular intervals during every important or prolonged operation, especially as a guide to the degree of shock, is admitted to be important by all anesthetists.

The anesthetist should give quick warning of any serious fall in the blood pressure, which will enable the surgeon to decide for or against transfusion, for or against attempted extirpation of a brain tumor, for continuing or quickly terminating an operation. This decision can thus be made with scientific accuracy far more surely than by observation of the general physical appearance of the patient. Accurately known blood pressure is of greater value than the rate or quality of the pulse, and as pointed out by Harmer, gives warning from 5 to 20 minutes earlier than the pulse. Moreover, in the doubtful cases it is the most useful.

Prior to operations the anesthetist as well as surgeon should make himself familiar with the condition of the heart, kidneys, blood pressure, hemoglobin, and any unusual condition: should

see that the mouth, tongue, teeth and tonsils are in proper condition and that provision be made to prevent chilling of the patient,—an important point never to be overlooked. Chilling and hemorrhage are the most potent factors in producing shock. Chilling by cold solutions and by alcohol used in pre-operative preparations do harm, as demonstrated by Harmer.

The anesthetist should provide against certain dangers common to all anesthetics, such as false teeth and other foreign bodies in the mouth, the prevention of paralysis of the musculospiral and other nerves from pressure or from abnormal positions of the arm or leg. I have had one non-fatal case of hemiplegia occurring a few hours after etherization. It is possible but not certain that this was a direct result of the increased blood pressure. Several other similar and sometimes fatal cases have been reported. It is to be remembered that in a few cases a hemiplegia has occurred shortly before the time set for operation. Had the hemiplegia occurred only a few hours or days later it might have occurred during the operation and have been (erroneously) attributed to the ether.

During operation the anesthetist should attend strictly to his own business and especially remember that the first half hour is the period of greatest danger. He should glance at the operation only from time to time, not to study the operation, but in order to anticipate the need for lighter or deeper anesthesia and when the anesthetic may be stopped. Of course he should keep himself constantly informed of the general condition of the patient by observation of the respiration, the most important function of all, of the blood pressure, pulse, pupil, color, and condition of the skin as to sweating.

I believe that an *anesthesia chart* should be kept in every case—even for a brief etherization. How elaborate this should be is a debatable question. The American Surgical Association could do good service, as Lilienthal has suggested in a letter to me, if through a committee it should prepare a standard chart adapted to most hospitals and most anesthetists. I am persuaded that a chart tends to concentrate the attention of the anesthetist upon his "job" and make him more careful. In a few years such charts would also furnish us with very valuable and extensive statistics. The form should be full enough to make it valuable and to compel the average anesthetist to make close and continuous observation, yet not so elaborate and detailed as to defeat its own object. Some especially expert anesthetists would prefer a more elaborate chart for more detailed observations. The American Surgical Association might also prepare this fuller form and each anesthetist could make his choice.

On first seeing the charts used by Boothby¹⁴ I was staggered by their apparent complexity. When analyzed, however, I found there was less than one observation per minute. In prac-

¹⁰ Anest.-Association, p. 97.

¹¹ Prog. Med., December, 1912, p. 218.

¹² Med. News, March 2, 1895, p. 125.

¹³ Annals of Surgery, 1901, Vol. XXIV, p. 329.

¹⁴ Jour. Pharmacol. and Exp. Therap., March, 1914, p. 329.

tice, as I have observed, Boothby easily records them all himself in a quiet leisurely fashion. Instead of distracting attention from the patient, these records fix the anesthetist's attention much more closely upon the patient's condition than if no chart is used. The occasional anesthetist will hardly be able to utilize any but the simplest chart.

If it be objected that a chart, and especially a full one, is a great deal of trouble, I answer: "Giving ether is a serious business, always attended by possibility of danger. Life may depend on the carefulness of the anesthetist, and this is surely worth any amount of trouble."

One feature of the chart of the Massachusetts General Hospital is exceedingly valuable, viz.:—that there is a first or pre-operative part to be filled in by the house officer (surgical or medical), who has had charge of the patient, giving most of the data the anesthetist should know beforehand; a second part relating to the data and conditions during operation to be filled in by the anesthetist; and a third post-operative part to be filled in by the nurse in charge of the case immediately after operation. A *duplicate carbon copy* should be made, the original to be filed with the notes of the case; the copy with the consolidated "Anesthesia Records."

Here the question arises whether a doctor or a woman nurse is in general the more desirable anesthetist. No hard and fast rule can be laid down. Surely no legislative action is called for, though it has been actually proposed. If one has an Alice Magaw (Kessel) or a Florence Henderson of the Mayo Clinic* or a Sister Ethelrida of Murphy's Clinic the decision is easily in favor of the trained nurse. If, however, one has such skilled doctors as we find especially here in Boston and other of our large cities the decision is reversed.

The nurse lives in the hospital and can see the patient at all times. She can soothe the timid patient, who is more often of her own sex, better than most men. She is more vigilant in observing small details. She will be less likely to be lured away from the rôle of the professional anesthetist than a man, who too often uses anesthesia merely as a stepping-stone to private surgical practice. A doctor, however, because he has studied medicine, is more thoroughly equipped than a nurse (until her experience runs into hundreds of cases) to appreciate possible or even impending dangers. Moreover, the doctor is less apt to be upset and "flustered" by a sudden perilous emergency. The best solution of all perhaps is an intelligent and alert woman doctor, such as Dr. Isabella C. Herb in Bevan's Clinic. Such Herbs, however, do not grow in every surgical garden.

Personality, intelligence, zeal and quick wit may easily be worth more than greater knowledge.

For two admirable and practical papers see Alice Magaw, *Surg., Gynecol. and Obst.*, 1906, Vol. iii, p. 795, and *Collected Papers*, Mayo Clinic, 1905-09, p. 567; and Florence Henderson, *St. Paul Med. Jour.*, February, 1914, p. 74, and *Collected Papers*, Mayo Clinic, 1913, p. 701.

In order that medical men and women shall devote themselves to anesthesia as a specialty, the public must be taught that safety lies in having an expert anesthetist, and that like any other expert, if he is to obtain a living as such, he must be well paid, otherwise he cannot devote his whole time to this specialty.

I might add also that the profession itself does not yet sufficiently appreciate this same point. Roberts¹⁵ cordially endorses this view. The peril he so valiantly attacked is gradually passing away.

One of the real but infrequent dangers of ether is its *inflammability*. I should probably omit this because of its infrequency had I not had personally what might have been a very serious accident.

Nearly everybody thinks that the vapor from a *volatile* substance of course rises upwards. The etherizer must never forget that the vapor of ether is *heavier* than air and falls downwards. Saturate a bit of gauze with ether. Hold the back of the hand first *above* the gauze and then *below* it and you will never forget that ether vapor falls. In 1863, after Gettysburg, in a large military hospital of 3000 beds in pavilions built wholly of wood, I was trying to secure a large bleeding vessel just above the inner end of the clavicle. The only available light was five candles stuck in five augur holes in a square block of wood and held necessarily very near the ether cone. Suddenly the ether flashed afire, the etherizer flung the glass bottle of ether (it was before the days of our present tin cans) in one direction and the blazing cone fortunately in another. We narrowly escaped a serious conflagration. Why did I not use chloroform, which is non-inflammable, in conditions well known before I began to operate? I fear I must admit gross thoughtlessness. My only consolation is that the patient suffered no harm. Neither he nor I was burned and he recovered without further incident.

So happy an outcome does not always occur, for there are on record a number of cases of more or less serious burns of both patient and surgeon. In one case, when the switch of an electric hand light was turned on to observe the color of the face (the patient being prone) the spark ignited the ether.

"Inflammability of the patient" might also be mentioned as a possible danger to the *surgeon*. Here again I speak from two personal experiences. In one, the patient in his early frenzy, disengaged himself suddenly from the etherizer, scattered the assistants and was about to assault me, when fortunately, a strong Irish orderly who, again fortunately, was standing behind him, so that the dazed patient was not aware of his presence, seized him around the waist and held him till the stage of excitement quickly passed away. Though bound like Samson with many withes, four strong men and the etherizer a few minutes later scarcely prevented his reduc-

¹⁵ The Anesthesia Peril, *Therap. Gaz.*, Feb. 15, 1908.

ing the table to firewood in a second attempt to "get" me.

The other case I relate especially as a warning that no one should ever give ether without the presence of another person, except in emergencies when such help cannot possibly be obtained.

Many years ago I had to open an abscess in a young man. The etherizer did not appear, and as the patient was suffering I unwisely gave him the ether alone. He had taken only a few inhalations when he was seized with the delusion that I was about to do him harm. With one sweep he threw the ether cone away, leaped up, seized a chair and swinging it high above his head was ready, nay determined, to brain me. As he was an athletic six-footer, and as he stood between myself and the door, fight and flight were equally impossible. I lost no time, you may be sure, in entering what I believe the lawyers call a plea of "confession and avoidance"; a confession of my folly, and a lively avoidance of my enemy. I have always accepted the axiom that two bodies cannot occupy the same space at the same time, but ever since that "episode," as Artemus Ward would have called it, I have been equally convinced that one body can be in two places at the same time. The only refuge I did not seek, was under the bed, and the evident reason for my not achieving that ignominious retreat was that my legs would have broken before I could have attained its friendly protection. Don't hint at a "*mauvais quart d'heure*." Less than two such "bad minutes" more than satisfied me and I am sure would have fully satisfied you.

The incident, which I can now blithely portray as a comedy, thus perhaps making its lesson less quickly forgotten, came perilously near to ending as a tragedy. Had the uplifted chair not been an impediment as well as a weapon, and had I not been forty years younger and forty pounds lighter, you would probably be listening to some other orator today.

In the case of women patients the rule never to give ether alone should be absolute, for delusional dreams do occasionally occur during anesthesia and are honestly believed after recovery. A charge of assault may easily follow either as a result of this sincere belief, or as a means of blackmail. If no witness was present the only evidence can be the positive assertion by A and the equally positive denial by B. How can the most intelligent jury be sure to decide aright? Moreover, if sudden death should occur, a third person as a witness would evidently be most desirable.

Unfortunately I have to confess my own delinquency in not keeping any record of my etherizations. I must, therefore, rely upon my own and my assistants' memories as to any fatalities. Two deaths from chloroform stand out very clearly in my memory, and had I had any from ether I feel quite certain that I should not

have forgotten so deplorable an event. I have had several very narrow escapes, but after a most careful review of my cases and conferring with Drs. DaCosta, Taylor and Spencer, who have etherized at least 75% of all my cases, we are all four so fortunate as not to be able to recall a single case of death, either immediate or remote, from ether.

Three of my patients have almost been drowned by an "inundation of mucus." One was a boy three or four years old whose mouth, shortly after the operation was begun, looked as if he were blowing soap bubbles. The loud bubbling respiration and his cyanosis could not be misinterpreted. He was saved by the simple expedient of holding him upside down by his heels. Frothy watery mucus poured in a stream from his mouth and nose. In a few moments the operation could be resumed and was completed without further trouble. The second was a man who was similarly rescued by Dr. Taylor's mounting the table, placing the man's legs over his shoulders and thus almost completely inverting him. The third case—a woman—was fortunately in a hospital and on a suitable table. She was at once placed in the extreme Trendelenburg position and quickly relieved. I mention these because I have seen reports of several deaths during operation, which, so far as I could judge, might have been prevented by a similar simple treatment, which is always available.

This "drowning" by mucus, as Connell has pointed out, is most likely to occur in the narrow zone between a light subconscientious anesthesia and a profound and asphyxial anesthesia. In that same zone also vomiting and consequent aspiration pneumonia are serious dangers.

The dangers on the cardiac side I need not describe in detail as Dr. Finney¹⁶ considered them fully in 1901 and I have little to add. I may be allowed a moment only to say that I would far rather operate on a case with a bad heart than with bad kidneys. Finney also called attention to the infrequency of deaths from heart disease under ether as compared with their great frequency in the general community. Patients with any cardiac disease of course run greater risks than those with healthy hearts, but as Ochsner has well said, such cases "are safe because they are considered especially unsafe" and therefore extra care is given them.

The chief danger is from myocardial rather than from valvular disease. I may cite a single case as evidence that valvular disease may not be so great a danger as is sometimes believed.

The worst case of valvular disease I have ever seen I operated on in January, 1888,—a woman then 62 years of age with marked tricuspid and mitral regurgitation. I resected the inferior dental nerve for unbearable tic. Ether was very carefully given and no trouble arose. In 1895 at nearly 70 years of age, she required a second operation for a recurrence. Had I not

¹⁶ Trans. Coll. Phys., Phila., 1901, 13.

done the first operation myself I might almost have doubted whether the jaw had ever been touched, so perfectly normal did the bone appear and so apparently normal were the nerve and its canal. Her valvular disease had become far worse. Prof. H. A. Hare kindly took charge of the ether. In both operations the Allis inhaler was used. During the second operation the external jugulars were enormously distended and the blood from the wound was very dark, especially toward the end of the operation. Hare writes me: "It was the most serious case of valvular disease that I have seen take an anesthetic. Neither have I ever seen such marked tricuspid regurgitation nor such extraordinary pulsation of the liver in any case, much less one that has been anesthetized. It is interesting to note that the administration of just enough ether to keep her under acted as a stimulant to her heart so that her pulse improved. It was only toward the latter part of the operation that the regurgitation became so great that intense cyanosis developed." Yet she was out of bed on the third day and went home on the sixth. She died two and a half years later. She was a patient of Drs. S. Weir and John K. Mitchell. The latter made the *post mortem* and reported that the right auricle itself was as large as a good sized heart and held the entire fist. The mitral orifice admitted the tips of four fingers, the tricuspid the thumb and three fingers. The pericardial sac was entirely obliterated.

The *respiratory dangers* are even more to be feared than the cardiac. During anesthesia the chief danger is paralysis of the respiratory center; after anesthesia a post-operative pneumonia.

The studies of Haldane, Priestly, Poulton and others in England and of several observers, notably Yandell Henderson of Yale, in this country have brought prominently before the profession the danger of *Acapnia*, i.e. the lack of carbon dioxide.* This gas, formerly regarded only as a noxious waste product, is now believed to be the irritant which calls into activity the extremely sensitive respiratory center.†

Poulton¹⁷ by forced breathing for two and a half minutes before the British Physiological Society, produced such a dangerous acapnia in himself that several of the physiologists expressed alarm for his life and at least one had to leave the room.

When a patient struggles or screams while being etherized, thus over-ventilating the lungs and dangerously diminishing the carbon dioxide, if

the etherizer becomes nervous and gives the ether intermittently, and especially if in these conditions any considerable amount of ether be suddenly poured on the inhaler, it may easily be enough to cause death by reason of its concentration. It must be clearly understood that not the amount of ether inhaled, but its *concentration* in the respired air, is the chief danger. Even two or three deep inspirations in such conditions are fraught with danger not only to the respiration but to the heart.¹⁸ Herein lies one of the chief merits of the Connell anestheticometer, as such a sudden concentration is impossible.*

In acapnic cases Henderson suggests a very simple means of temporary re-breathing in order to supply the needed carbon dioxide by holding a (grocer's) paper bag over the mouth and nose for a time. In an emergency the two hands could be placed over the patient's mouth.

It is also possible that not only may there be an insufficiency of the stimulating carbon dioxide but in certain conditions there may be a reduction in the irritability of the respiratory center itself which may add to the danger.† Future experimental research may reveal more clearly these causative conditions and also the means of avoiding them.

"The great hyperpnea produced by a rapid fall in the oxygen pressure of the inspired or alveolar air is not due to the direct effect of want of oxygen on the respiratory center, but to that of the carbon dioxide present. . . in the blood. The action of this carbon dioxide is reinforced by the acid or other products produced by the want of oxygen, so that the threshold pressure at which the carbon dioxide excites the center is lowered."¹⁹

But besides its effect on the respiratory center, an excessive loss of carbon dioxide, it is claimed,²⁰ produces paresis of all unstriated muscular fibers, including those of the vascular system. The blood then accumulates in the internal vessels, and so is followed by facial pallor instead of normal pinkness. To guard against this paresis and consequent pallor Bryant and Henderson,²¹ who regard acapnia and anoxemia as "the anestheticist's Seylla and Charybdis," propose that his "sailing orders" should be "keep the patient pink." Whether this theory is correct or not, the order is well worth obeying. Under the Equator, however, and in our equatorial fellow citizens I fear that it would hardly be an attainable tint.

In the intestines, it is claimed that this paresis of the unstriated muscle halts peristalsis, thus

* The foregoing and some other later statements seem simpler and more easily understood by others than physiologists than if they were in every detail more technically exact.

† As noted by Campbell, Douglas, Haldane and Hobson (Jour. Physiology, 1913, Vol. xvi, p. 301) the facts recently brought forward by Hesselbach point clearly to the conclusion that what the respiratory center really responds to, when it responds to CO₂, is the balance of H-ion concentration in the blood; and as an increase of 2 m.m. of CO₂ pressure corresponds to a scarcely measurable increase in the H-ion concentration of blood, it follows that the respiratory center is extremely sensitive to changes in the H-ion concentration. (See also Douglas and Haldane, Jour. Physiol., 1909, Vol. xxviii, p. 420.)

¹⁷ Johns Hopkins Hosp. Rpts., August, 1910, p. 235.

causing the gas pains which sometimes are a post-operative complaint and may be a serious danger.* But if acapnia is prevented by a preliminary dose of morphin and atropin and by moderate rebreathing during etherization, normal peristalsis, it is claimed, will persist at the end of a laparotomy.

The greatest respiratory danger of ether is *post-operative pneumonia*. While ether itself is, I believe, a moderate irritant to the air passages (in spite of Rovsing's assertion), undoubtedly the principal cause of such post-operative pneumonia is aspiration of the contents of the mouth. Kelly²² of Liverpool and Hölseher²³ by putting coloring matters in the mouth have placed the fact of such aspiration beyond doubt. Kelly has shown equally clearly that one of the great advantages of endotracheal insufflation is that this aspiration practically does not occur.

The aspirated matter will consist of the oral mucus (not seldom, be it remembered, laden with the pneumococcus), the discharges from any lingual, oral, dental or tonsillar ulcer or abscess, and the contents of the stomach, which have been vomited but not wholly ejected. Hence the necessity too little appreciated both by surgeons and anesthetists of getting the mouth, tongue, teeth and tonsils in proper condition before operation.†

Besides this, the utmost care should be used by the anesthetist to prevent vomiting if possible. "If on minimal [not, observe, maximal] dosage, the breathing becomes shallow with an occasional deep breath," vomiting is impending. (Connell.) Should it occur, the anesthetist should promote the speedy and complete escape of the vomitus by turning the head sidewise in extension and thus prevent or diminish aspiration. The prevention of aspiration pneumonia lies largely in the hands of the anesthetist. One of my correspondents confesses to having had two deaths on the table from inhalation of the vomitus during recovery from the ether.

But we must not attribute all the pneumonias which follow ether to the irritation of the ether itself, to its mode of administration or even to aspiration. Armstrong²⁴ has shown that pneumonias are especially frequent in cases of septic foci existing at the time of operation and attributes these pneumonias largely to septic emboli, an opinion re-enforced by Beckman²⁵ of the Mayo Clinic. In operations in the upper abdomen such emboli are especially to be feared. This is due partly to the natural inhibition of diaphragmatic breathing and therefore of full expansion of the lower part of the lungs by reason of the pain.

* Such "gas pains" have not been very common in my own experience and observation.

† I have seen foul roots of old teeth which should have been removed some days before the operation extracted by the surgeon at the end of an operation.

Pneumonias may also follow local anesthesia, in which there can be no question of aspiration. Gottstein²⁶ and Mikulicz²⁷ both report larger percentages of pneumonias after local anesthesia than after general anesthesia. The experience in the Mayo Clinic confirms this observation. The probable reason is that the weaker and more serious cases have had local anesthesia. "Most of the lung complications have developed in patients who have been operated on for carcinoma, especially of the stomach, and the autopsy has shown fine metastatic growths in serial sections of the lungs.*"

Anuria fortunately is not a very frequent sequel of ether, but is a very serious one. Ether as a rule decreases the urine for a day or sometimes longer. I always watch the bedside chart with anxiety for the first two or three days to ascertain the urinary output. As a rule after 24 or 48 hours there is a moderate increase. I have lost two patients from anuria. The first was a case of nephro-lithiasis, occurring unfortunately just a year before the discovery of the x-rays. I knew of course of the moderate frequency of bilateral renal calculus, and that temporary suppression sometimes followed unilateral nephrotomy. In this case during the first 28 hours after the nephro-lithotomy only eleven ounces of urine in all were secreted; in the next four days only twenty-five to twenty-eight ounces daily. In spite of vigorous treatment, the amount fell to fourteen, and then to three and a half ounces with absolute suppression for the last 36 hours. She died on the eighth day. I had anxiously considered the question of an exploratory operation on the other kidney, but there was absolutely no clinical evidence of any stone there. If no stone were found at a second operation and she had died, I should forever have had a burden on my conscience. The x-rays would have decided the question and might have saved her life, for a calculus in the other kidney was found at the *post mortem*.

The other case had a large sarcoma of the shoulder. Removal of the entire half shoulder girdle was the only possible operation. He died in 31 hours, never having secreted a drop of urine.

Chace²⁸ reports the examination of the urine in 125 consecutive cases. Two cases—with no albuminuria before operation—died from suppression on the seventh day. In the great majority both of normal and abnormal kidneys there is happily only a temporary diminution, but the amount of the urine should always be most carefully recorded and vigilantly watched.

At present it is impossible to predict such suppression. The remedies, such as they are, are well known but may easily be of no avail.

Glycosuria also may follow etherization, as was first shown in dogs by Hawk²⁹ in 1904. As

²⁹ Arch. Int. Med., July, 1911, Vol. viii, p. 89.

a rule it is only temporary. Hawk and his associates have shown that this glycosuria, at least in dogs, is especially dependent on diet. A carbohydrate-free diet always was followed by glycosuria while after a mixed diet there was none. That this glycosuria is not wholly the result of etherization (at least in cats) but may be in part an "emotional glycosuria," caused by the excitement attending operation, was first pointed out by Cannon,³⁶ and has since been confirmed by others both in this country and in Germany. Henderson and Underhill³⁰ attribute the glycosuria to acapnia. Higgins and Ogden³¹ have shown that injuries of the head were followed by glycosuria in nearly 10% of the cases.

In diabetics it would therefore be advisable to use nitrous oxid and oxygen or, if possible, local anesthesia, since ether might precipitate a fatal diabetic coma.

Acidosis. Recently the dramatic fatal cases reported by Brewer, Beesly and Bevan, and the researches of Crile, Hawk, Bevan and Favill; of your Boston men, Ladd and Osgood, Peabody, Kelly, Brackett, Stone and Low, and numerous others, have focussed attention upon acidosis and its various results, especially acetonaemia.

Could anything be more distressing than such a case as Brewer's?³² A boy of 12—a successful operation for appendicitis—everything practically normal till the third night after operation. Then pulse, temperature, and wound all being normal, sudden attacks of terror awaking him from sleep, his screams heard all over the building, increasing somnolence in the intervals, next a sweetish breath, repeated vomiting, acetone and diacetic acid found in the urine and death in 32 hours after the first piercing scream! Such a case breaks a surgeon's heart.

The pathological changes in acidosis are especially pronounced in the liver, so much so that Bevan and Favill call it an "hepatic toxemia." Crile† and others have shown that this is a local pathological instance of a more widely distributed normal process. All the activities of the body, every "transformation of energy" produces acid by-products, which in turn must be neutralized if life is to be sustained. The kidney, as pointed out by L. J. Henderson,³³ separates the non-volatile acid from the base of these acid by-products of metabolism, excretes the acids in solution and returns the bases to the blood to be used over again in neutralizing additional acid. The volatile acid—carbon dioxid—escapes by the lungs. The H-ion concentration of the blood (PH) is an index of the acidity of the blood and of its carbon dioxid³⁴ content. This carbon dioxid stimulates the respiratory center

and also causes an increased output of adrenalin. Crile claims that his histologic and chemical studies have shown that the changes in acidosis are limited to the brain, the adrenals and the liver. Certainly these organs and especially the liver do show marked changes. "While in acidosis the H-ion concentration of the blood is not altered, its *reserve alkalinity* (i.e. the ability to retain normal reaction despite the addition of acid) is decreased to a measurable amount.³⁵ Carbohydrate starvation especially favors acetonaemia.

Kelly³⁰ examined the urine in 400 cases in the Boston City Hospital and found 46 which showed acid intoxication in 17 different disease conditions. Ladd and Osgood³⁷ in their important paper showed that in 120 patients etherized with the Blake cone, acetonaemia was found in varying degrees and proportionate to the length of the etherization in 106 (88.5%), whereas in 102 by the open method this percentage fell to 26%, or less than one-third as many as when the cone was employed—a very serious indictment of the cone method. Gatch³⁸ has emphasized this danger and I think explained the reason for it.

In some cases the symptoms,—persistent vomiting, sweetish (acetone) odor of the breath, peculiarly pink lips, dry tongue and mouth, give us warning. Examination of the blood and urine will convert suspicion into certainty.

The administration of water, glucose and sodium bicarbonate, the lessening of all physical and psychical conditions which increase the transformation of energy are the best preventive remedies. If there is no manifest and speedy improvement no general anesthetic should be given. Local anesthesia should be employed.

But in not a few cases no symptoms whatever betray its approach until the storm bursts in all its fury. Future studies and experiments on animals it is to be hoped may furnish us with warning signals that may enable us to prevent or vanquish this not very common but terrible danger.

What now is the conclusion of the whole matter? In my opinion "straight ether" by the open drop method on an Allis inhaler or a simple mask is by far the best and safest routine anesthetic. I am glad that such staunch upholders of more elaborate and accurately scientific methods of administration, as Boothby and Connell, both upheld this dictum. This is especially the method of choice for doctors who only occasionally give an anesthetic, because the margin of safety with ether is so wide.

In some clinics from which I have replies in exact figures, many thousands of patients have been etherized especially by this method without

³⁸ Trans. Amer. Surg. Assn., 1911, p. 198.

a death. Alice Magaw (Kessel) and Florence Henderson have to their credit respectively 22,000 and 20,000 administrations without a death. But other clinics have a mortality of one in 5000, one in 3000 to one in 451,* thus bringing the average mortality down to 1 in 7706. Inclusion of the late deaths would make the proportion much less favorable.†

Evidently we ought to and must attain better results, especially when the British surgeons and anesthetists have shown us that they can be realized. To attain these better results we need in my opinion:

1. Many professional anesthetists.
2. The use of an anesthesia chart in all cases.
3. The collection of statistics, best by the American Surgical Association at intervals of five years.
4. Instruction of all medical students in the theory and practice of anesthesia.
5. Straight ether by the open drop method as a routine method instead of mixtures and sequences. I believe all of the latter to be more dangerous than ether.
6. More accurate dosage of the ether by the anesthesiometer as a gas on the basis of its anesthetic tension, *i.e.* the partial pressure of the ether vapor in the respired air.

Meyer and Gottlieb²⁹ frankly attribute the great majority of accidents to "faulty management and incautious dosage of the anesthetic," and again (pp. 74-5) to "the administration of too high concentrations of the anesthetic." A knowledge of this concentration or "anesthetic tension" cannot be obtained by observation. It must be by exact measurement in millimeters of mercury.

In spite, therefore, of the splendid results in certain most competent hands, I believe that others less skilled would achieve better results by some such "instrument of precision," and the most skilled and successful would find great comfort in this more exact knowledge.

Science began with the substitution of the balance, the yardstick and the clock, for even the most accurate guesses as to weight, dimension and time. In anesthesia the same I feel *must* hold good.

Of all the apparatus I am acquainted with, the Connell anesthesiometer appeals to me as the best. It deals with ether in the form in which it actually reaches the patient's lungs, that is as a gas and not as a liquid. The tension is easily and quickly regulated according to the needs of the patient. The alcoholic, the child, and the

adult all require to be saturated to the same ether tension in order to saturate their tissues up to the point of anesthesia.

Inquiry as to whether any deaths had occurred in cases in which the anesthesiometer had been used disclosed only one, a patient at the Brigham Hospital operated on by Dr. Harvey Cushing. Dr. Walter M. Boothby, than whom no one could be more careful or more skilful, gave the anesthetic. The patient was a man with a very large cerebellar tumor pressing upon the medulla. He died from respiratory failure eight minutes after the beginning of the anesthesia. It is very clear, I think, that neither anesthetist, the anesthetic, nor the apparatus was responsible for the fatal result. It was due to the situation and size of the tumor.

I have never seen so smooth an etherization as one by Boothby with the anesthesiometer for nearly two hours in one of Cushing's brain cases. The patient's breathing was inaudible throughout, in sharp contrast to the moderately stertorous breathing and coughing of another patient anesthetized elsewhere a few days later by the Roth-Dräger apparatus. The anesthesiometer looks complicated, but its management is easily mastered and it then fulfils exactly the requirements just quoted. In fact, I think it is the only apparatus that does. It will be useful only to those who can afford the expense and who are constantly engaged in giving ether, especially in hospitals. It will not supplant the open drop method as a routine method to be used by the great majority. The very accuracy of the apparatus is a temptation to place too implicit reliance upon it, forgetful of the fact that the reaction of the patient and the disease cannot be accurately predicted.

EVERY CASE OF ANESTHESIA IRRESPECTIVE OF THE METHOD EMPLOYED REQUIRES UNREMITTING WATCHFULNESS FROM FIRST TO LAST.

Endotracheal and endopharyngeal insufflation are most valuable additions to our methods.*

Thoracic surgery, which for years had lagged behind all other departments of regional surgery, has suddenly broadened and improved by leaps and bounds, as a result first of the differential pressure chambers and later of insufflation methods, so that now all the organs in the chest are freely accessible. One important note of caution sounded by Cotton and Boothby⁴⁰ I must repeat and loudly,—there must always be provided a *safety valve* to prevent excessive pressure and serious damage to the lung and the right heart.

What of the future? New anesthetics and improvements in our present methods, possibly even the discovery of the ideal anesthetic, will give us, I hope, a new, a safe and an agreeable

* The hybrid Latin and Greek terms "intra-tracheal," "intra-pharyngeal," etc., should be discarded for "endotracheal," "endopharyngeal," etc., derived wholly from Greek. Trachea, pharynx, etc., are not Latin words, but simply Greek terms transferred into Latin as we have transferred menu, chauffeur, etc., into English. Imagine our writing "intra-canditis" or "intra-metrium!"

⁴⁰ BOSTON MED. AND SURG. JOUR., March 28, 1912, p. 486.

* As to this report from one of the ablest of American surgeons, it is but just to state that he only recently began to keep systematic anesthesia records. It is evident from the details he gives that very exceptional cases happened to be operated on during the short period since he began his records. We most all admire his honesty in giving the exact figures.

† All the British and American figures as well as Gurlt's and Rossini's (see page 832) are to some extent a matter of definition of what is a "death from ether." One surgeon (or anesthetist) would admit and another report the late pneumonias and allied "status lymphaticus" (Henderson, Trans. Amer. Surg. Assn., 1911, p. 230), those from intercranial pressure, suppression of urine, etc.

²⁹ Pharmacol. Clinical and Exp., Translated by Hasley, Lippincott, 1913, p. 68.

anesthetic ere the centenary of anesthesia occurs on October 16, 1946.

Finally: In glorious, yea inspiring, contrast to the work of destruction promoted by other departments of Science, as shown in the present horrible war, is the blessed work of our Guild. In war as in peace, winning victory after victory over disease and death, we devote all our knowledge, skill, and ingenuity, century after century, to the solace and service of Humanity.

Original Articles.

PREGNANCY AND DIABETES MELLITUS.

By ELLIOTT P. JOSLIN, M.D., BOSTON.

[From the Department of Theory and Practice, Harvard Medical School.]

A SMALL quantity of sugar in the urine during pregnancy is so common an occurrence as to attract comparatively little attention, and the frequency with which it is met probably depends upon how often it is sought. As a rule in such cases the sugar permanently disappears soon after confinement, although it may recur with succeeding pregnancies, and ultimately a severe form of diabetes may develop. With our present knowledge it is quite possible that such an outcome could be prevented by active treatment of the glycosuria from the very start.

The gloomy outlook for pregnant women showing large quantities of sugar became somewhat modified when it was recognized that these cases could be divided into two groups, based on the appearance of sugar before or after the pregnancy began. If pregnancy occurred in diabetic patients the outlook was considered far more serious than when diabetes first appeared during pregnancy. A somewhat more hopeful view of the whole situation was taken by Eshner (*American Journal of Medical Sciences*, 1907, Vol. 134, p. 375) and by Stengel (*Penn. Med. Journal* 1907-8, Vol. 11, p. 960), and still more recently by Neuman (*Ztsch. für ärztl. Fortbild.*, 1913, Vol. 10, p. 367), who reported six successful cases.

The experiments of Carlson and Günzberg (*American Journal Physiology*, 1914, Vol. 36, p. 217) are interesting rather than encouraging. Whereas total extirpation of the pancreas in non-pregnant dogs results promptly in the onset of pancreatic diabetes, complete pancreatectomy in pregnant bitches near term is not followed by hyperglycaemia and glycosuria as long as the fetuses are alive and the placental connections are not severed. At the onset of labor blood sugar begins to rise and characteristic

pancreatic diabetes is established on the completion of the delivery.

It is not surprising that so little progress has been made in the treatment of pregnant women with diabetes, because progress in the treatment of uncomplicated diabetes has been slow. However, the introduction of the therapeutic methods of Naunyn and von Noorden, who incorporated in their own the best of former modes of treatment, brought about improvement, and pregnant patients with sugar in the urine have now been subjected to the same kind of rational treatment which is employed with considerable success in ordinary cases of diabetes, and of course these methods have been greatly improved of late by Allen's rational development of Guelpa's work. But it is only fair to say that the general practitioner still has a horror at the discovery of a considerable quantity of sugar in the urine during pregnancy. For this reason, I shall record in detail Case No. 812, in which diabetes of moderate severity occurring during pregnancy was successfully treated, and I shall refer to another case (Case No. 307) seen in consultation with Dr. J. G. W. Knowlton, and an unusual case (Case No. 106) seen many years ago with Dr. F. W. Taylor, which he then treated most carefully according to the method of treatment then generally employed. In addition, I can report two severe cases (Cases Nos. 608 and 671) in young women, which were unsuccessful but might have progressed more favorably, and another case (Case No. 604), which was not severe, but was neglected and died with uremic complications. Finally, there is Case No. 854, alive, but with one unsuccessful pregnancy. Among these severer cases there were ten pregnancies and three children who are alive and well. In the same connection, a group of seven cases of pregnancy, in two of which (Cases Nos. 698 and 318) small quantities of sugar were found before conception took place, but in all of which sugar was moderate throughout, will be summarized. Among these cases there are eleven pregnancies and nine children are well at present. Such a record does not appear on the whole encouraging, but a study of the case histories leads to quite the opposite conclusion.

CASE No. 812, a physician's wife, aged 31 years, first seen December 29, 1914. The examination of the urine showed a slightly acid reaction, specific gravity 1038, no albumen, sugar 6.4%, no diacetic acid. There was no family history of diabetes; the patient had had measles, mumps, whooping cough,

and a rather peculiar case of typhoid. She was married at 21, and one year later had a stillborn child. In June, 1914, she became pregnant. Shortly afterwards her husband was called away from home. Upon his return in December, 1914, during the sixth month of pregnancy, sugar was found in the urine, but it was impossible to determine when it first appeared.

The patient felt well except for slight dyspnea, presumably due to her condition; polydipsia and moderate polyuria existed, but the appetite was decreased rather than increased; the bowels were constipated. Physical examination: the highest weight was 179, and the present weight 169 pounds; normal pupillary and patellar reflexes; heart normal; pulse 100; blood pressure 130; considerable oedema of the lower extremities, especially the right leg, and an abdomen consistent with a pregnancy of six months.

The case appeared to me most favorable to attempt to carry through to term. The patient had previously been fat, and this spoke for a mild character of the disease. The polyuria was not great, although the per cent. of sugar was high. Furthermore, the patient was a doctor's wife. Both she and her husband thoroughly appreciated the situation, each had a cheerful temperament and instantly showed that they would follow directions. I was especially encouraged to allow the pregnancy to go on because of many favorable results with even severe diabetic patients undergoing major surgical operations. It was agreed that the patient should enter the New England Deaconess Hospital and remain there until danger was over or until confinement occurred.

The obstetrical side of the case was placed in the hands of Dr. J. C. Hubbard, who wrote me on January 7, 1915, as follows: "It seems to me that the problem offered by this case is one to be solved by you. Obstetrically she is in excellent condition and there is no reason why she should not go through her confinement all right. I feel that I am not qualified to express an opinion about how much the presence of sugar complicates the situation. From my point of view, however, one must remember this,—that should it seem advisable to you to end the pregnancy now, the difficulty in starting uterine contractions and bringing on labor might put her through almost as much as a delivery at full term, either normal or hurried as much as possible."

During the week intervening between the first visit and the entrance of the patient to the hospital, no alteration in the diet was made, and from the accompanying chart it will be seen that the percent of sugar underwent no change.

Following entrance, the carbohydrate in the diet was gradually decreased from approximately 130 grams to 45 grams and the patient was allowed a very moderate quantity of protein and fat. Sugar then disappeared, but the diacetic acid rose to three plus and the ammonia, which at entrance was 1.3 grams in 24 hours, rose to 3.0 grams. With 8.0

grams of sodium bicarbonate and a slight increase in the carbohydrate, the ammonia fell to normal, where it remained until just after confinement. The sodium bicarbonate was eventually omitted. The tolerance for carbohydrate rose to 100 grams. The protein was kept in the neighborhood of from 75 to 100 grams—a little over 1 gram per kilogram body weight.

When it was seen that the acidosis did not wholly disappear upon this diet, the total quantity of food, which was largely in the form of fat, was decreased to such an extent that the patient was kept from gaining weight. In other words, when one considers the co-existent pregnancy, the patient was kept upon an undernutrition diet.

The weight at the time of confinement, March 24, 1915, was 156½ pounds, as compared with 157¾ pounds at the sixth month. During the last three months of pregnancy the patient was in as good health as any normal pregnant woman. She had the freedom of the hospital, took daily walks, and by her cheerful temperament contributed much to the happiness of other diabetic patients with whom she was associated. As I had lost no case of diabetes in this hospital since August 29, 1914, she gained confidence in the manner of treatment.

The blood sugar on February 13, 1915, after dinner, amounted to 0.25%. The urine upon this day showed a non-quantifiable trace of sugar by the Benedict test, and there was a trace of diacetic acid. The carbohydrate ingested was 110 grams. On February 18, 1915, fasting, but with the same quantity of carbohydrate in the diet, the blood sugar was 0.16%. The urine still showed a trace of non-quantifiable sugar, and the diacetic acid persisted.

The method of delivery was carefully considered by Dr. Hubbard, who finally advised a Caesarean section, as set forth in his letter of February 8, 1915: "One more word about the method of delivering this patient. From my point of view it would seem desirable to have the labor put her through the least possible strain. It is not at all probable, I imagine, that she will have any more children, therefore the delivery should take the least possible chance with the baby. A Caesarean fulfils both these requirements. It saves the woman all muscular exertion. She gets through with less ether, and it is the easiest possible way for the baby, for there is no risk of twisted cord, which may occur in even the most easy vaginal delivery. A Caesarean would be done on a definite date. Would such a definite time be of any advantage to you in the way of dieting her in preparation? The time for the beginning of labor normally would, of course, be far from definite. You see I favor a Caesarean. If you should agree, I should like to have an opportunity of talking with her and explaining the necessity for suggesting such a delivery." The advice was accepted by the patient and the Caesarean was performed on March 24, 1915, the approximate normal date for confinement. In my absence immediately prior to delivery, as well as for the next few days, the patient was under the care of Dr. F. Gorham Brigham, to whom I am much indebted.

The reaction of the urine was acid throughout. Albumen at no time exceeded the slightest possible trace, and casts were never present in the sediment except just after delivery.

The urine for the 24 hours preceding the operation was as follows: 1710 c.c., specific gravity 1012, acid, slightest possible trace albumen, nitrogen 11.3 grams, ammonia 0.9 grams, no sugar. In the sediment there were no casts or pus and only an occasional red blood corpuscle. The diet for the same day contained about 120 grams of carbohydrate, and was as follows:

Breakfast. Bacon, 2 eggs, 1 orange, 30 grams bread, 15 grams oatmeal, 120 c.c. milk.
Dinner. 90 grams roast beef, carrots and peas, 120 c.c. milk, coffee jelly (made without sugar) 15 grams nuts, 1 apple.
Supper. 1 egg, asparagus, 15 grams oatmeal, 120 c.c. milk, 15 grams toast, $\frac{1}{2}$ orange, 60 grams potato.

The blood pressure, which was 130 on December 29, 1914, had remained essentially the same, and was 125 on the day before delivery.

It had been previously agreed that if acidosis developed prior to the termination of labor a Caesarean section would be performed under local anaesthesia. Fortunately, this was not necessary.

During the 24 hours following delivery a trace of sugar appeared in the urine, but the ammonia remained at 0.8 grams and the nitrogen at 8.8 grams. Diacetic acid was present, and the sediment showed numerous brown granular and a few hyaline casts. Upon the second day there was 0.2% of sugar by the Benedict test, but the urine was 0.6% levo-rotary on account of the acidosis, which was proven by the presence of 2.2 grams of ammonia and a marked diacetic acid reaction. The sediment showed an occasional hyaline cast. Upon the third day the urine showed only a trace of sugar, but was 0.8% levo-rotary, the ammonia was 1.8 grams and the nitrogen 8.7 grams. Upon the fourth day it was essentially the same; there were no casts. Thereafter, the sugar disappeared, and up to October, 1915, has never returned in a quantitative amount.

Upon the day of delivery and the two following days the patient was practically fasted on account of the return of sugar and diacetic acid. The diet was then gradually increased, beginning first with a small amount of carbohydrate and protein, and the fat was limited to approximately 50 grams. Within a week the diet had been brought back nearly to what it was prior to delivery.

The baby was normal in every way. The weight at birth was eight pounds, and he steadily gained, reaching 13 pounds on July 30. It is frequently maintained that diabetic patients cannot nurse their babies, or that they ought not to nurse them. Nursing was easily maintained in this case until the middle of June, when the milk rather abruptly ceased. The patient was at that time in New Hampshire, and other circumstances may have played a factor to bring this about. The weights of mother and baby are recorded on the chart. The weight of the patient six days before delivery was 156 $\frac{1}{2}$ pounds. On April 8, fifteen days after delivery, it was 130 $\frac{1}{2}$ pounds.

Nitrogenous equilibrium was evidently maintained during the weeks before and after confinement.

The blood sugar on April 11, fasting, was 0.2%, in contrast to 0.16% on February 18, 34 days before confinement.

CASE No. 307, aged 34, first seen December 15, 1909, in consultation with Dr. J. G. W. Knowlton. The family history was negative. The first pregnancy began in May, 1909, and sugar was first discovered six months later, when the urine of November 30, 1909, showed specific gravity 1045, acid, no albumen, sugar 1.7%. Polydipsia, polyphagia and polyuria were present. Possibly the explanation of the appearance of sugar may be attributed to the diet, which was rich in carbohydrates—cakes, jellies and candy. There were no digestive, respiratory or nervous symptoms, but dyspnoea was present on exertion and also insomnia, which was attributed to pains in the legs, although oedema was absent.

Physical examination showed normal pupillary and patellar reflexes, no oedema, pulse 100, blood pressure 130. Apex of heart in mamillary line with a systolic murmur at the base. The abdomen presented a normal appearance for six months pregnancy. The former highest weight was 124 pounds, but at the sixth month of pregnancy it was 155 $\frac{1}{2}$ pounds. The urine of December 15, 1909, showed specific gravity 1018, acid, no albumen, sugar 1.0% and diacetic acid slightly plus, no casts, pus or blood.

The patient was given the following diet: Strict diabetic diet, one and one-half pints milk, half a pint of cream, vegetables in the 5 and 10% carbohydrate groups freely, a tablespoonful of vegetables from the 15% group, one orange, one ounce of bread, two ounces of potato and two tablespoonfuls of oatmeal, or approximately 130 grams of carbohydrate.

On February 16, 1910, Dr. Knowlton reported that sugar disappeared on January 25, but was replaced by albumen and casts. The albumen increased to 0.3%. Anasarca appeared the first of February. Labor commenced at 3 a.m., on February 7, 21 hours later high forceps were used, but the baby was born dead. Sugar disappeared following confinement. In May, 1915, I learned that the patient had been severely ill with diabetes during the preceding winter.

It is worthy of attention that this patient survived confinement, despite the appearance of marked anasarca and 0.3% albumen. If Dr. Knowlton could be so successful at this period with such a case, it is obvious that with the advance in treatment of diabetes and nephritis during the last six years, still better results might be obtained. In the light of Case No. 812, reported above, it is possible that an early Caesarean section might have saved the child.

CASE No. 106, aged 39, was first seen on November 22, 1905, with Dr. F. W. Taylor, who reported the patient's last pregnancy in the BOSTON MEDICAL AND SURGICAL JOURNAL of March 2, 1899, Vol. 140, p. 205. The family history was negative. The patient was always well except for frequent micturition since childhood—a story frequently volunteered by diabetic patients—which became more marked at the age of 29. Married July, 1896, at the age of 30. Miscarriage the following September. The second pregnancy began in December of 1896, and

in June, 1897, 8.5% of sugar was found, which gradually decreased. On July 3, 1897, the urine was acid, specific gravity 1010, trace of albumen, no sugar. Labor began August 19, and the child was extracted with forceps; 13 years later this child was reported to be well-developed, vigorous and healthy. Two weeks after delivery the urine was again examined and found to contain sugar, which persisted. The patient was occasionally seen during subsequent years by Dr. Taylor and on March 13, 1905, the urine was found to contain 6.0% of sugar and no albumen. The weight of the patient was 108.

Pregnancy occurred for a third time in April, 1905, but this time the quantity of sugar was not as easily controlled as before. It is interesting that the patient was *fasted* one day by Dr. Taylor in his efforts to lower the sugar, and as a matter of fact it did decrease to 2.1%, but in August was 6.7%. In October, 1905, the sixth month of pregnancy, 5.8% of sugar was present. On November 20, the sugar had disappeared, but albumen had developed. Nausea was present and there was marked epigastric discomfort, so that the patient was accidentally fasted. Tenderness was present over the upper part of the uterus. The pupils were normal; there was no drowsiness or acetone odor; teeth fair; tongue slightly dry; heart and lungs normal; pulse regular. 104, with slightly increased tension. The uterus was well above the navel. It was decided to deliver the child at the very first sign of approaching coma, and three days later this was accomplished. Sugar remained absent from November 20 to 29. On November 27, two days after confinement, the nausea ceased and the patient began to eat. *It is interesting to note that accidentally starvation treatment was practised for a period of seven days.*

In December the urine showed 80 grams of sugar in the 24 hours, and pulmonary tuberculosis had developed. The percent of sugar, however, fell to between 1.0 and 3.0%, and in January was less than 1.0%, disappearing on January 15 entirely. On January 16, 1906, the patient died.

In Dr. Taylor's opinion, the diabetes developed during the second pregnancy. The favorable result of the second pregnancy despite the large quantity of sugar in the urine, even under therapeutic methods far inferior to those of today, encourages one in the treatment of other similar cases. The employment of starvation by Dr. Taylor in 1905 showed how carefully he treated the case, and the fact that the patient survived a third confinement, although extremely ill, may have some connection with the artificial seven days' fast which her nausea caused. Finally, the disappearance of sugar from the urine when tuberculosis appeared, is in accordance with what often happens, and is recorded by me in the *American Journal of Medical Sciences* (see Case No. 344, Vol. 4, p. 474) and still more in detail in *Carnegie Publication*, No. 176, p. 55, 1912, Case R. Benedict and Joslin, *Metabolism in Severe Diabetes*.

CASE No. 608, age 28, first seen April 22, 1913. The father has diabetes. One brother is deaf and dumb. Mother and one sister well. Nothing of note was recorded in the past history. In July, 1912, sugar was found, accompanied by polydipsia

and polyuria. The weight in August, 1912, was 174. Despite her knowledge of the existing diabetes, the patient married February 8, 1913, and promptly became pregnant. At the time of observation the quantity of urine was approximately 3000 c.c., and a single specimen on April 23, showed specific gravity 1030, very slight trace of albumen, 2.8% sugar, diacetic acid + + + +, no casts, pus or blood. On April 25, the urine amounted to 3000 c.c., acid, specific gravity 1026, slightest possible trace of albumen, sugar 3.0%, diacetic acid + + + +. When first seen the patient was drowsy, short of breath, and greatly annoyed by a parched tongue, thirst, constipation and bleeding hemorrhoids. She was weak and tremulous, all over. Pupils reacted and heart and lungs were normal; pulse 96 and blood pressure 115. The abdomen was negative save for tenderness in the right iliac fossa; the uterus was not felt.

It developed that soon after the discovery of the disease in July, 1912, the patient was put under dietetic treatment by a physician experienced in diabetes, but that recently she had given up treatment and placed herself under the care of a clairvoyant. The patient died in coma shortly after being seen. This case is recorded because it probably is typical of many others, and in part accounts for the gloomy prognosis usually held for pregnant diabetic patients.

CASE No. 671, age 25 years, first seen November 25, 1913, was a Jewish woman, who probably developed diabetes in April, 1912, although unrecognized by herself. She was married in June, 1912, and the disease was discovered in August, 1912. At the first visit the urine contained 7.2% of sugar. She was advised not to become pregnant, but pregnancy did take place in January, 1914. The urine did not become sugar-free, and an abortion was successfully performed by Dr. Friedman in March, 1914. I later learned that she again became pregnant and in October, 1914, committed suicide.

CASE No. 604 was seen by me once in consultation on April 14, 1913. The patient and baby were lost, but there is considerable reason to believe that they might have been saved. The age of the patient was 28 years. Her mother died of diabetic gangrene at 40, one sister became insane the first week of April, 1913, having shown sugar two years before; one sister died of Bright's disease with mental symptoms, and one sister was fat and well. The past history of the patient showed measles, mumps, whooping cough, chicken pox. She had been married eight years. Present illness: On February 22, 1909, sugar was found in the urine, but with dieting disappeared. The patient was free from sugar at the time of the first visit, as she had also been in the previous December. She became pregnant for the first time in February, 1913. On account of the family history of diabetes, which in my experience usually implies a mild type of the disease, on account of the absence of sugar and on account of the nervous upset which at that time the interruption of pregnancy would have caused, both because of her sister's case and her own first pregnancy, I advised that the patient be kept under close observation and the pregnancy allowed to continue. As the family physician was to be away some months, definite directions were given to the patient to report to a specified physician at short intervals. Instead,

the patient did not report. June 10, and June 18, the urine, which was examined by the physician and his assistant who were to take immediate charge of the case, was found sugar-free. The husband, however, took another specimen to an osteopath, who said that he found sugar, and for weeks the patient was placed under his observation. Upon the return of the original family physician in August, during the sixth month of pregnancy, 3.8% of sugar was found and a slight trace of diacetic acid, and soon albumen developed. In the seventh month, September 27, on account of urgent symptoms, the pregnancy was terminated, the patient dying a few hours later in coma—probably uremic—and the baby was lost. Ether was used. Shortly after the husband committed suicide on her grave, but it is only fair to record that a previous attempt some years before with chloroform failed. The accompanying chart shows the later course of the disease.

CASE No. 854, age 33, first seen April 15, 1915. The onset of diabetes was in 1911, and sugar was discovered in December of that year. An uncle died of diabetes, father of cardiac disease, mother of paralysis, two brothers and one sister well, six brothers and sisters of diphtheria, one sister of appendicitis. In August, 1912, the patient was delivered of a child, now well. On December 13, 1914, she had a stillborn child at term, but had a hard confinement.

The patient said she was sugar-free during the first month of pregnancy, in April, 1914. In April, 1915, three examinations of the urine were made by me, and showed sugar varying between 0.4 and 0.6%. The specific gravity varied between 1013 and 1017, the slightest possible trace of albumen was present, and no diacetic acid. Evidently the case was mild in type throughout. A partial explanation of this was that the patient's highest weight was 173. It had fallen to 149 in April, 1914. Physical examination showed normal reflexes, no acetone odor, teeth normal, pulse 112, blood pressure 130, a systolic murmur at the apex of the heart, lungs normal and nothing abnormal felt in abdomen.

The remaining seven cases represent a milder type of diabetes. Too much sugar, however, was present in the urine to allow one to consider them simply transitory glycosurias, and furthermore, in two of the cases sugar was demonstrated before pregnancy occurred. It is not strange that four of the cases occurred in physicians' families.

CASE No. 256, age 27, first seen May 29, 1909. Family history negative. Measles, scarlet fever, pos-

sible chorea and considerable anaemia at 23. Jaundice at 24. Married at 25. One healthy child. The second pregnancy began in November, 1908, but sugar was not discovered until May 26, when the patient had an attack of vertigo with black spots before the eyes, lasting for ten minutes. The urine then showed specific gravity 1038, acid, no albumen, sugar present. The diet was promptly changed, and when I first saw the patient on May 28, two days later, the 24 hour urine was 1420 c.c., specific gravity 1027, slightest possible trace of albumen, no diacetic acid, and 0.8% of sugar, or 11 grams in the 24 hours. The sediment showed no pus, casts or blood. The diet of the patient was gradually changed from one containing 160 grams of carbohydrate to one containing about 125 grams, at which it remained until after confinement. Sugar was constantly present until confinement on August 20, when the patient was successfully delivered of a boy. September 18, the sugar had disappeared, and from that time on remained absent and has continued so until the present time. A third pregnancy occurred one year later.

The physical examination of June 7, 1909, showed nothing abnormal. The weight of the patient before marriage was 112, and while carrying the first baby was 150; during the sixth month of the second pregnancy it was 140. The high specific gravity in May,—1038—shows that the per cent. of sugar at this time also must have been high, and it is fair to infer that if this patient had not been promptly treated the disease might have taken a serious turn. As it is, one likes to believe that it illustrates the efficacy of prompt, early treatment.

CASE No. 732 showed sugar in the urine during the sixth month of pregnancy on September 3, 1903. Diacetic acid was absent. Sugar was again found on September 5, and amounted to 0.1%. On September 20 and October 5 it was 0.5% by the fermentation test. It was 0.4% on November 9, and 0.7% on December 4. At no time did diacetic acid appear, and albumen did not exceed an extremely slight trace. The delivery, on December 26, 1903, was uneventful, and on October 24, 1904, the urine was free from sugar, as it also was on February 16, 1906, and March 19, 1906. Patient and child are well today, but no subsequent pregnancy has occurred.

CASE No. 712, first seen March 19, 1914. The mother and sister died of apoplexy; father, 3 brothers and 7 sisters and one child 7 years old are well. Past history: Muscular rheumatism and mumps. Pregnancy began October 27, 1913. Sugar was first

CASE NO. 712.

(The urine was acid throughout and the albumen never exceeded a very slight trace.)

discovered March 9, 1914, and there was no evidence that it had been present for a long time. The urine showed 1200 c.c., specific gravity 1030, no albumen, sugar 1.5%, no acetone, no casts, an occasional red blood corpuscle. The urine had not been examined since the previous confinement 7 years before, when it was normal. Subsequent examinations are given on the following chart. Present illness: The patient complained of no symptoms save those of pregnancy. Physical examination: Highest weight 128, usual weight 125, and weight on March 19, 1914, 120. Patient rather thin, and somewhat excited. Pupils equal and react, no acetone odor, teeth normal, knee jerks normal, pulse 112, blood pressure 130, apex of the heart in mammillary line with systolic murmur at base and apex, liver extending a finger's breadth below the costal margin.

The diet of the patient was restricted to between 100 and 125 grams of carbohydrate. She was successfully confined at term. Examinations of the urine were made in August, October and November of 1914, and January, March and April of 1915, but at no time had sugar returned in quantitative amount.

CASE No. 698, age 36, became pregnant in June, 1913. Father, mother and 2 brothers are well. Past history showed appendicitis at 18, ill for 5 months. One child well. In 1905 marked gastric hyperacidity, but there was no sugar in a 24-hour specimen of urine. The patient, however, was said to have shown sugar in the urine on various occasions in 1911. On December 4, 1913, the urine showed specific gravity 1018, acid, no albumen, no diacetic acid and no sugar. On January 14, examination showed 0.6% of sugar. Subsequent analyses are recorded on the chart. The patient went to term and was successfully confined.

This case and the next one to be reported are interesting in that sugar was demonstrated in the urine before pregnancy commenced, and yet the course of the pregnancy was uneventful and the diabetes did not increase in severity. What would have happened had the diet not been restricted is problematical. Like former patients, this patient was kept on a diet containing approximately 125 grams of carbohydrate.

CASE No. 318, age 27, first seen February 24, 1910. Past history negative. In March, 1908, while teaching school and nervously tired out, sugar was found in the urine. At this time the patient was taking much carbohydrate at night before retiring with the hope of gaining weight; she was previously unaccustomed to sweets. After six to seven months upon a diabetic diet the sugar disappeared. She was married in February, 1909. At the time of the first visit she was not pregnant, but the urine contained 0.4% of sugar. The full analysis was as follows: 520 c.c., specific gravity 1028, acid, very slight trace albumen, 0.4% sugar, no diacetic acid; in the sediment no casts or pus, rare normal blood cell. The patient eventually became pregnant, but sugar was absent throughout, although it returned 2 weeks after confinement in considerable quantity, and up to 1912, the last record amounting to 0.2%. She has since had another child and sugar returned during pregnancy, but disappeared following confinement. She keeps sugar-free, but her physician is closely following her diet.

CASE No. 438, age 25, is sharply in contrast to the one just reported, for instead of sugar disappearing during the pregnancy, it appeared during three successive pregnancies, and was absent in the intervals. I am indebted to Dr. Franklin S. Newell for some of the data. Sugar appeared in the first pregnancy, but ceased immediately after confinement. In the summer of 1910 it occurred, but a miscarriage took place. The urinary analysis of August 29, 1911, showed acid reaction, specific gravity 1019, slightest possible trace of albumen, sugar 0.6%, no diacetic acid; the urine of September 14, 1911, showed 2000 c.c., acid, specific gravity 1020, slightest possible trace of albumen, sugar 1.0%, no diacetic acid. The nitrogen was 12.6 grams,—no casts, pus or blood. In March, 1913, the patient considered herself pregnant, but the urine at that time and at subsequent examinations soon after failed to show sugar, and time showed that pregnancy did not exist! Pregnancy did occur in December, 1913, and a trace of sugar showed throughout, only to disappear after confinement in September, 1914.

Thus at three pregnancies sugar has been present, but in the intervals sugar has been absent. The absence of sugar at a time when the patient considered herself pregnant but was mistaken is also interesting.

Foster (Nellis B. Foster, *Diabetes Mellitus*, 1915, p. 99) records a case similar to the above, in which "there had been a pronounced glycosuria during two pregnancies which had entirely subsided after the birth of each child so that there was no sugar in the urine and no dietetic restriction was employed. During the third pregnancy there was observed not only glycosuria, but also a moderate increase of thirst, and following the termination of this pregnancy the sugar secretion and the symptoms persisted."

CASE No. 788, age 35, first seen November 9, 1914. Father had diabetes, but at the age of 73 is considered well. Mother died of diabetes and heart disease. Two brothers are well, but a sister has malignant disease and sugar is also present in the urine. Another sister is well. Past history: Patient

has eaten a considerable quantity of sweet food. A mild pneumonia at 32; bronchitis and tonsillitis several times. During the first pregnancy, at the age of 33, she showed traces of sugar at eight and one-half months, even though she dieted for diabetes. On account of threatened symptoms delivery was brought about at eight and one-half months, but the baby lived only 24 hours. Following confinement mental symptoms developed, and the patient was at a sanatorium for nearly two months. At the end of this time the urine was free from sugar.

The patient again became pregnant in September, 1914. On November 9, 1914, the urine showed 0.4% of sugar, no diacetic acid, slightest possible trace of albumen, no pus, casts or blood. A trace of sugar was present two days later. The general appearance of the patient was excellent; pupils and knee jerks normal, pulse 92 and regular, blood pressure varying from 130 to 135, and at a second examination was 145. The area of the heart was normal, but there was a systolic murmur at the base and apex. Otherwise the physical examination was negative. On account of the severe mental symptoms at the first pregnancy, the persistent glycosuria, the elevated blood pressure and the marked hereditary tendency, it was considered best to terminate the pregnancy, which was done on November 17, 1914. Sugar was absent from the urine on February 3 and on April 10, 1915.

Out of the seven cases of moderate or severe diabetes associated with pregnancy, it is true that four are dead,—one by suicide (Case No. 671), one (Case No. 604) with uremic manifestations which can reasonably be ascribed to neglect, a third (Case No. 608) died in coma, pregnancy having developed after diabetes had existed for a year, but treatment of which was neglected, the patient later being under the care of a clairvoyant, and the fourth (Case No. 106) in which the patient successfully went through her first pregnancy in 1897 with a healthy child, but again was confined and the child lost in 1905, the patient dying two months later of pulmonary tuberculosis. But it is also true that of the three remaining cases one is in exceptionally good health, free from sugar, and has a normal child six months after delivery; that another is in a tolerable condition, having been pregnant three times but with only one child now living; and that the remaining case (Case No. 307) is alive, although severely ill with diabetes six years after confinement.

All of the seven cases with moderate quantities of sugar in the urine are well.

On the other hand, it must be remembered that of the seven severe cases only one, Case No. 812, occurred at a time during which modern treatment could be carried out. It is a fair inference to draw from the other cases that pregnancy in this instance would not have progressed so favorably had the disease developed when knowledge of treatment was less advanced. A study of this case makes it also a fair inference that Cases Nos. 608 and 604, under careful treatment, would not have terminated fatally. I do not think that Case No. 621 would have

been successful under any condition, because of the mental state of the patient. Of the four cases which died, three were known to have sugar in the urine before pregnancy took place, but I personally do not believe that this fact had much to do with the unfavorable course of the disease, although I would agree to the statement that pregnancy occurring in diabetes is far more serious than diabetes occurring in pregnancy. It must be acknowledged, however, that the diabetes appeared in Case No. 106 after pregnancy began, as well as in the other three severe cases which survived, and that Case No. 106 lived eight years after her first pregnancy.

It is important to note that the seven milder cases presented quantities of sugar which were considerable in amount; that four of these cases were in medical families and so the disease presumably was discovered early, and that the favorable course of the disease with them can justly be explained by their constant supervision. Of these seven cases, two showed sugar before pregnancy, but this apparently did not exert an unfavorable influence.

The favorable outcome of Case No. 812 encourages one to believe that even if a patient had a somewhat severer type of diabetes, it could be successfully combated. Several expedients which could have been tried were not necessary. For example, fasting was not employed; at confinement instead of ether, gas and oxygen could have been used, or the Caesarean section could have been performed with local anesthesia; and furthermore, the patient need not have gone to full term.

CONCLUSIONS.

From a study of these cases it would seem that the secret of success in the treatment of pregnant women with sugar in the urine is:

1. To have the patients under constant supervision throughout the course of the pregnancy and for some months after confinement. The cause of the death of Case No. 604 may well be attributed to the neglect of this precaution.
2. Treatment should follow exactly the same methods which are employed in the treatment of the usual case of diabetes.
3. Even when sugar appears to a slight extent in pregnant women, it should be carefully watched and controlled by diet.
4. The advantages of a Caesarean section should be borne in mind.
5. Whereas ether anesthesia may work well, it is probably not so safe as gas and oxygen. If ether should be used, as brief an anesthesia and as little ether as possible should be employed.
6. Finally, many statements occurring in the literature of pregnancy and diabetes must be revised. Pregnancy in diabetes does not demand immediate abortion, even if acidosis is present. If pregnant diabetic cases are suitably managed, they will very likely abort less frequently. It cannot yet be accepted as proven that pregnancy

aggravates a diabetes. It is quite possible that the reason for a patient with diabetes becoming worse during pregnancy is simply due to the ingestion of an unusual quantity of food. Reliable data upon the carbohydrate tolerance of diabetic patients before and after pregnancy are not available, although Maase (*Char. Ann.*, Vol. 35, p. 33) records a single such instance. Nursing is not contraindicated following confinement, for the diversion which it affords the patient may offset the extra demands thrown upon the metabolism. Too few data have been accumulated regarding the blood sugar of pregnant women to warrant conclusions. The same statement may be made about the alleged excessive weight of children of diabetic mothers. The next few years may show that pregnancy can take place in diabetic patients far more readily than has been supposed. It is certainly true that with the improvement in the treatment of diabetic patients, diabetic women will be less likely to avoid pregnancy.

SURGICAL SPECIALTIES IN HOSPITALS.*

BY PAUL THORNDIKE, M.D., BOSTON.

*Assistant Professor of Genito-Urinary Surgery,
Harvard Medical School.*

THE enormous advances which surgery has made during the last half century have made it inevitable that many men should interest themselves in some special branch or branches of surgical work, to the exclusion of others. This narrowing of one's field of activity is not to be condemned, provided it has taken place through a natural process of selection and has been based upon a proper knowledge and experience of the whole surgical field. The so-called specialties have not only made distinct places for themselves, but at the present time apparently are making these places more secure both in the minds of the profession and of the general public. Whether such specialties have sufficient reason for their existence, or whether they exist for the best interests of surgery and the surgical profession is not for our discussion here. They do exist and flourish. Let us consider them in their surgical relations, both from the hospital and from the medical school point of view.

A hospital is commonly said to have three great fields of usefulness,—the efficient cure of the sick; the proper use of its material for advancing the cause of science; and the teaching of doctors, students and nurses. For the efficient cure of the sick in any but small hospitals there must be some basis for a division of cases into groups, as one service of men and nurses cannot properly care for more than a certain number of cases—50 or 60. In making such divisions it would seem obvious that if the cases are grouped according to their kind, those caring for them, both doctors and nurses,

* From the *Harvard Medical Bulletin*, page 21, May, 1915.

will acquire an excellence of technical routine which will be both economical and efficient, and thus will be of the greatest advantage to both the hospital and the patient. This is so evident, that in many of the hospitals where such special departments of work are more or less frowned upon, the conditions arrange themselves to some extent automatically, and one finds a certain sort of patient being admitted to Dr. So-and-So's service because he is known to be especially interested and expert in the care of that sort of case, and is anxious to give all the time and skill he possesses to the study of it. So that from the patient's point of view it would seem as though such special departments are necessary in every hospital. The same may be said with relation to research work and other scientific use of surgical material. The special worker will evidently take more interest in the best and completest use of his material and will get the best results for his profession and for himself from such study.

Again, it seems to be the common opinion today that every good hospital should be a teaching hospital, and therefore that its organization must be based in some degree upon medical school needs. In the school, as in the hospital, the wide range of subject matter, to be properly administered, demands division of material; and in the school, much more than in the hospital, up to the present time, this division into departments pertains, because it has proved the obviously best solution of the teaching problem. But for the school's best interest, this same division into departments should maintain to a corresponding degree in the hospital because the best teaching demands such groupings of patients, just as the best hospital efficiency and economy demand it. So that theoretically it would seem to be at once for the best interest of patient, hospital and medical school that special services shall exist.

All very well, but where is this theory leading us? How far shall we go with it? Is the general surgeon to disappear? Are we to have specialists in all branches of surgery? Are hospital house-officers and nurses to be brought up as specialists from the start, with a practical hospital education in one line of work only? Are the members of our visiting staffs to be confined to a small field of work, or at all events to a much smaller field than meets with their inclinations and desires? Are the orthopedic men, the aurists, and the urologists, to be followed by many other special men, each lopping off a portion of the work formerly performed by the general surgeon? Obviously not, although it would seem almost as though this were so at the present moment. It is a hard problem and probably it is one which will gradually develop and settle itself, without much guiding from the profession. It would seem, in spite of all our theorizing about specialties in surgery, that the general surgical service must exist for many years to come and that the development of various spe-

cial departments in surgery must be a problem for the individual hospital concerned, both from its hospital and from its medical school aspects.

At the Boston City Hospital, where for many years special departments in surgery have been in little favor, an interesting experiment is being tried on lines suggested by Dr. George H. Monks. There had never been a genito-urinary service at the hospital. He suggested that such a service be organized, somewhat as follows: Every other genito-urinary case, male or female, is admitted to the 4th surgical service of twenty beds devoted exclusively to the care of urological cases. This leaves the other half of such cases to be distributed among the three other surgical services, so that these may not be deprived entirely of their genito-urinary cases. It is hoped that the development of the special service will attract enough extra patients of this sort to the hospital so that the special service will grow in size and in the quality of its cases, while at the same time the other services will maintain as many such cases as they had before. The service, so far as its visiting staff is concerned, is on a par with the other surgical services, and all members of the staff, in order of their seniority, are privileged to choose months of work on this, as well as on the other services; so that the men most interested in urological work may choose this service, and yet others less interested may also choose occasional work on this service if they so desire and in order of their seniority. The house-staff of two is appointed for six months—three months junior and three months house-surgeon. This short service is arranged with the hope of attracting superior men of previous surgical training, who desire experience in this special line of work and yet who feel that they cannot devote longer periods of time to it. So far this hope has been justified. The special service has general supervision, but not complete control of the urological room in the out-patient department, so that out-patient surgeons, in the order of their seniority, may choose months of work in this room if they desire, just as they have done always. This results, as in the service in the house, that the men most interested in and identified with urological work will naturally choose this out-patient service, so far as their rank entitles them to do so.

It will be seen at once, that while such an organization does not create an ideal special service, it does provide the hospital with an adequate urological service, from both the patient's and the hospital's point of view, and it does make a teaching unit which can utilize its material adequately for medical school purposes. It does this without conflict with other surgical services and it deprives no one on the staff of material which he desires to retain for his own purposes. This urological service has passed its first year of existence and it is steadily progressing in interest and value. May it not very possibly be the forerunner of similar services for other branches of surgical work?

OBSERVATIONS UPON THE ETIOLOGY AND TREATMENT OF HEART DISEASE.*

BY PAUL DUDLEY WHITE, M.D., BOSTON.

From the Medical Service of the Massachusetts General Hospital, Boston, Massachusetts.

The relationship of the more important abnormalities of the heart beat to etiology and treatment has been studied in the cardiac patients seen at the Massachusetts General Hospital during the year August 1, 1914, to August 1, 1915.

Auricular fibrillation produces the most important disorder of cardiac rhythm—absolute irregularity, perpetual arrhythmia, or *delirium cordis*. It consists of an absolutely irregular ventricular response to a fibrillary activity of the auricular walls in the place of normal regular ventricular response following auricular contraction. It is indicative of a damaged myocardium. One hundred cases of auricular fibrillation were found in the wards and in the outpatient department of the hospital during the year.

Pulsus alternans, consisting of the alternation of strong and weak pulse beats either with normal rhythm or after premature beats, is the most important pulse index of myocardial exhaustion, much more significant than the *delirium cordis* of auricular fibrillation. One hundred patients with alternation of the pulse, with rates nearly all below one hundred per minute and none above 125, were seen in the wards and outpatient department of the hospital during the course of the year.

The present communication is chiefly concerned with the comparison, with regard to etiological factors; of these two series of cases with each other and with one hundred consecutive cases with heart disease and normal cardiac mechanism, *i.e.* normal rhythm without alternation, over the age of ten years seen at the hospital during the same year. I shall also discuss the etiology in seventeen cases of heart block of high grade made up of four cases of complete block, two of which had also lesions of the right branch of the bundle of His (as shown by electrocardiograms) and thirteen other patients with bundle

branch block. Of these thirteen cases three had also auricular fibrillation and seven had alternation of the pulse. Finally there will be considered seven cases of auricular flutter, which is an uncommon type of very rapid and abnormal auricular action with which heart block usually of the two-to-one grade is associated. Premature contractions (the *extrasystoles* of old) and paroxysmal tachycardia I shall not consider here partly because of their relative unimportance and partly because hospital statistics in such conditions are incomplete and hence misleading.

The present series of cases of alternation of the pulse is the largest which has been studied statistically; for comparison I have summarized the cases recorded by Gravier,⁵ 38 of his own and 50 collected from the literature. The fibrillation cases are numerous enough to compare satisfactorily with Lewis' 152 patients as tabulated in the second edition of his "Clinical Disorders of the Heart Beat"; the patients with auricular flutter add appreciably to the 53 cases collected by Ritchie¹² from his own clinic and from the literature; and finally the instances of heart block of the bundle branch type (14 with right branch involvement and 1 with left) may be studied with reference to the series of 22 discussed by Carter.² A general comparison may be made as to etiological type with the six hundred patients recently analyzed by Cabot.¹

Sex and age. Tables 1 and 2 show the sex and ages of the patients of the present series and also of the cases recorded by Gravier,⁵ Lewis,³ Carter,² and Ritchie¹² for comparison.

TABLE I. SEX.

	Male	Female
Cardiac patients with normal mechanism	66	34
Patients with auricular fibrillation	56	44

* Read at the Heart Symposium of the Mississippi Valley Medical Association, Lexington, Ky., October 19, 1915.

In every group recorded in Table I, the male sex preponderates, most markedly in the series of heart block and auricular flutter. Cabot,¹ however, in his general analysis of 600 patients with cardiac disease found a very even division between sexes—49% male and 51% female. Also of seventeen children under ten years of age sick with endocarditis in the wards of the hospital during the year, eleven were female and six were male; these children all had normal cardiac rhythm except one, who showed auricular premature beats. From available data we may conclude that auricular fibrillation, auricular flutter, heart block, and *pulsus alternans* are more frequent in the male than in the female.

The age incidence in auricular fibrillation and in alternation of the pulse is strikingly similar, the fifth and sixth decades in each series pre-

(12%), and chloroform in one case (4%). A severe attack of typhoid fever was the only likely factor in one of the two flutter cases of doubtful origin in my own series. Besides producing flutter, diphtheria has been accused of causing heart block and auricular fibrillation.^{3, 6, 7, 9, 10, 11, 13.} Scarlet fever was directly responsible for the acute endocarditis found in two of the seventeen children with endocarditis under the age of ten years seen in the wards of the Massachusetts General Hospital during the year.

Arteriosclerosis apparently played a very important rôle in the production of alternation of the pulse in the cases recorded by Windle.¹⁴

Hyperthyroidism was present in the medical wards of the hospital in seventeen patients without alternation or fibrillation as well as in the five cases recorded in the table. The patients

TABLE III. ETIOLOGY.

	Total	Rheumatism						
		Mitral Stenosis	Syphilis	Arteriosclerosis	Nephritis	Hyperthyroidism	Congenital Heart	Doubtful
Cases with normal mechanism	54	28	21	7	7	—	5	6
Auricular fibrillation	48	22	4	26	5	4	0	13
Alternation of the pulse	15	8	14	32	29	1	0	9
Total per cent. of 300 cases	39%	19%	13%	22%	14%	2%	2%	
Heart block	4	1	1	12	0	0	0	0
Auricular flutter	4	2	0	1	0	0	0	2
Gravier's cases of alternation	14%		11%	10% +	47%			
Lewis' cases of fibrillation	66%	52%						
Lewis' cases of heart block	32%		11%					
Carter's cases of heart block	32%		18%	27%				
Ritchie's cases of auricular flutter (25 cases)	44%		16%		8%	4%		
Cabot's general series	46%		12%	16%	20%			

dominating. The age limits of alternation observed were 10 and 83, of fibrillation 21 and 83. Lewis⁸ in 1913 cited the reported age limits of fibrillation as 5 and 84 years. An analysis of 33 out of 45 cases of *pulsus alternans* found by Windle¹⁴ shows 31 over the age of 50 years. The comparison of the cases of normal heart beat with those of fibrillation and alternation demonstrates clearly what we should expect, namely that the older the patient with heart disease, the less likely he is to have normal mechanism and the more likely he is to have fibrillation or alternation.

Etiological factors. Table III shows the relationship of various etiological factors to the more serious disorders of the heart beat. The rheumatic group includes patients with cardiac damage following chorea, rheumatic fever, or tonsillitis.

It is well known that a close relationship exists between mitral stenosis and auricular fibrillation. In my series of 61 patients with this valve lesion 22 (36%) were fibrillating. Lewis⁸ reports that fibrillation was present in 22 (21%) of 106 out-patient cases of mitral stenosis.

Other causes than those recorded in the table among 25 of Ritchie's flutter series¹² were diphtheria in 2 cases (8%), influenza in 3 cases

showing the abnormal cardiac mechanism were chronic cases.

Excessive use of alcohol, tobacco, coffee, and tea apparently played no direct part in the production of the important disorders of the heart beat; a history of previous indulgence was obtained more often from the patients with normal cardiac mechanism than from those with serious disorders of the heart beat.

Eight of the one hundred cases with auricular fibrillation were of the transient or paroxysmal type. So far as I know none of these eight patients has developed a persistent fibrillation but it is probable that some of them will do so eventually. Of six cases of transitory *delirium cordis* reported by Fox⁴ in 1910, five developed permanent irregularity of the pulse. An acute pericarditis, possibly by direct irritation, accounted for the short paroxysms in one of my eight cases of paroxysmal fibrillation.

Twenty-eight of the three hundred cardiac patients with normal mechanism, auricular fibrillation, and alternation of the pulse were of unknown or doubtful origin. At times difficulty was experienced in placing the cases into groups of the various types, i.e. rheumatic, luetic, and so on, but reasonable accuracy was assured by

utilizing all data obtainable: past history, physical examination, urine examination, blood pressure estimation, the phenolsulphonephthalein test, the Wassermann reaction, eye ground examination, and the use of the Roentgen ray.

Observations upon treatment. Table IV shows the number of cases with physical signs of cardiac insufficiency among the three hundred patients with normal heart beat, auricular fibrillation, and alternation of the pulse. Also there are indicated the number of patients subjected to digitalis, morphine, venesection, and the change of diet to five small meals daily. Rest as complete as possible and the administration of digitalis were the therapeutic measures of prime importance in nearly all of the cases. Digitalis acted most favorably and rapidly in the patients with auricular fibrillation. It was given nearly always in the form of 0.1 gram (1½ grains) pills made directly from the Caesar and Loretz standardized leaf. This preparation proved very effective all through the year, results being obtained in a very few days after beginning its use. There were but two or three patients who were unable to take this preparation. In the urgent cases strophanthin, onobain, or digipuratum were used intravenously—in thirty-five patients in all: twenty-four with auricular fibrillation, ten with alternation of the pulse, and one with normal cardiac mechanism.

Morphine was used in patients who were decidedly uncomfortable—dyspnoeic and restless. Venesection was employed in the presence of marked venous stasis, cyanosis and dyspnoea. In addition to these therapeutic measures special diuretics such as diuretin and theocin and purgatives such as magnesium sulphate and elaterin were used as needed, especially for marked or persistent oedema. The change in diet to five small meals a day was frequently a useful adjunct.

TABLE IV.

	Physical signs of cardiac insufficiency.	Digitalis	Morphine	Venesection	Five small meals daily
Cases with normal mechanism	35	25	20	4	11
Auricular fibrillation	66	64	25	3	11

Total	151	133	67	11	34
Per cent. of 300 cases	50%				
Per cent. of 151 cases	88%	44%	7%	23%	

SUMMARY.

1. The male sex has been found to be more subject to auricular fibrillation, auricular flutter, heart block and alternation of the pulse than has the female sex.

2. The older the patient with heart disease the more subject he has been found to be to serious abnormalities of the heart beat.

3. Auricular fibrillation and alternation of the pulse occurred at the same ages, most frequently in the fifth and sixth decades.

4. Rheumatic hearts usually showed normal mechanism or auricular fibrillation, much less commonly *pulsus alternans*.

5. A considerable percentage (36%) of syphilitic hearts showed alternation of the pulse; few were fibrillating.

6. A patient with cardiac insufficiency in the course of cardiorenal disease was very apt to show *pulsus alternans*, either constant or more frequently only after ventricular premature beats.

7. Cardiosclerosis often resulted in the production of fibrillation and alternation.

8. Hyperthyroidism of long standing was sometimes attended by auricular fibrillation.

9. Alcohol, tobacco, tea, and coffee appeared to play no direct part in the production of serious disorders of the heart beat.

10. Two-thirds of the patients with auricular fibrillation, one-half of those with alternation of the pulse, and one-third of those with normal mechanism in the present series showed physical signs of cardiac insufficiency.

11. Digitalis was used in 88% of these decompensated cases, almost always in the form of pills of standardized leaves. Intravenous medication was used in urgent cases only.

12. Morphia was given beneficially in nearly one-half of the patients with physical signs of insufficiency, often one dose sufficing to give the patient the first comfortable night in weeks.

13. Venesection was found useful in a few urgent cases.

14. The change in diet to five small meals daily was often much appreciated by the patient.

Book Reviews.

S. Weir Mitchell, M.D., LL.D., F.R.S. 1829-1914. Philadelphia, 1914.

This privately printed volume consists of the memorial addresses and resolutions presented at

the special meeting of the College of Physicians of Philadelphia, held upon the death of Dr. S. Weir Mitchell, January 6, 1914. Besides the record of this meeting, it contains four minutes passed, upon this occasion, by the trustees and medical council of the University of Pennsylvania, the directors of the Library Company of Philadelphia and the trustees of the Jefferson Medical College. It also contains the record of a joint meeting in memory of Dr. Mitchell, held on March 31, 1914, by the College of Physicians of Philadelphia, the American Philosophic Society, the University of Pennsylvania, the Library Company of Philadelphia, the Jefferson Medical College and the Academy of Natural Sciences. Dr. James C. Wilson, president of the College of Physicians, presided at this meeting and addresses were delivered by Mr. Talcott Williams on Dr. Mitchell as a man; by Dr. William H. Welch on Dr. Mitchell as a physician and a man of science; and by Mr. Owen Wister on Dr. Mitchell as an author. Apart from the individual interest of all these addresses, the volume, as a whole, is of extreme value as a combined record of appreciation of Dr. Mitchell by his colleagues as one of the great physicians and men of letters whom this country has produced. An admirable portrait engraving of Dr. Mitchell forms the frontispiece of the book.

Old London's Spas, Baths and Wells. By SEPTIMUS SUNDERLAND, M. D., London: John Bale, Sons and Danielsson. 1915.

This volume, by the president of the Balneologic and Climatologic Section of the Royal Society of Medicine, is based on his presidential address before that body in November, 1914. This has now been expanded into a history of old London, with reference to its water supply, wells, baths, medicinal springs and spas. To the physician it is of interest not merely as a professional study of water supplies and of hydrotherapy, but as a local medical history of London with many allusions and collateral references to history of a general and non-professional character. It is charmingly illustrated with thirty-six full page plates, representing many scenes in and about London, both of the past and of the present. The text is agreeably written and will appeal immediately to non-professional as well as to medical readers. The volume closes with a valuable alphabetic bibliography of over fifty titles. In its editorial comment on Dr. Sunderland's work, the *Medical Press and Circular* quotes as follows from Thomas Dekker's famous description of London in one of his plays.

"O! London, Thou art great in Glory and envied in thy greatness. Thy Towers, thy Temples, thy Pinnacles are set about thine Head like a Garland of fine gold. Thy waters hang like fringes of silver upon the borders of thy Garment. Thou art admired like a Bride that drawest all men that look upon Thee to be in

love with Thee.' The waters are now most of them drained into the Thames, and the fringe is almost wholly invisible. Kilburn, Tyburn and other similar names perpetuate its memory, and to the observant eye local fogs still attest the subterranean presence of its components. The subject of these underground rivers is an interesting one; to some it is even absorbing. Perhaps Dr. Sunderland in his inimitable manner will some day tell us about them, too."

It is sincerely to be hoped that the author will comply with this editorial suggestion.

Nursing in Diseases of the Eye, Ear, Nose and Throat. By the Committee on Nurses of the Manhattan Eye, Ear and Throat Hospital. Second edition, thoroughly revised. Philadelphia and London. W. B. Saunders Company. 1915.

The first edition of this text-book by the ophthalmologic, otologic and laryngologic surgeons of the Manhattan Hospital was reviewed in the issue of the *JOURNAL* for Jan. 5, 1911 (Vol. elxiv, p. 26). In this second edition not only has the text been edited with a view to the elimination of obsolete material, but sections have been added on several new subjects, such as the preparation of surgical dressings, mental disturbances after operations on the eye and functional tests of the static labyrinth. This chapter on feeding and care of infants has been especially revised in the light of the latest teaching on this subject. The book is well illustrated with eighty-one text figures and should continue a valuable volume in the series of text-books for nurses issued by this publisher.

Compend of Human Anatomy. Revised by D. GREGG METHENY, M.D., L.R.C.P. and S., Edin.; L.F.P.S., Glas. Eighth edition. Philadelphia: P. Blakiston's Sons and Company.

The original edition of this familiar manual in Blakiston's series of so-called quiz compends was prepared by Dr. Potter. This eighth edition of Potter's work by Dr. Metheny maintains the merits and disadvantages of the original. The danger of such compendia as sole sources of information is one against which students need constantly to be warned; but properly used as a syllabus in conjunction with larger text-books, there is a legitimate field of use for an accurate and well-written work of this sort. The reviser is particularly to be commended for his sensible and conservative stand in the matter of terminology, adopting, as he has done, only those terms from the Basle nomenclature which seem entitled to survival. The book is illustrated with 139 text figures, many tables and sixteen useful plates of the arteries and nerves. With the reservations previously indicated, it may be recommended as a useful aid to students.

Manual of Embryology. By A. MELVILLE PATTERSON, M. D., F. R. C. S. London: Henry Frowde and Hodder and Stoughton. 1915.

From time to time the JOURNAL has published reviews of German and American works on embryology. This English textbook on the subject represents the author's lectures and demonstrations as professor of anatomy in the University of Liverpool. The work is divided into two parts, the first dealing with general embryology, the second with organogeny. In his introduction he wisely emphasizes the importance of the study of comparative anatomy and embryology, not only for the understanding of gross anatomy but for the intelligent interpretation of medical and surgical disease. Ontogeny, he points out, "is dependent on, and inextricably bound up with phylogeny." The prime agent in the production of abnormality is excessive or arrested development due to the precocity or subordination of certain of the factors concerned in embryologic evolution. Such abnormalities he differentiates from true teratologic conditions due to pathologic causes. The work is well written and arranged and the judicious use of black faced type facilitates emphasis and study. It is particularly to be commended for the figures, 304 in number, with which the text is illustrated. A few of these are in colors and all are models of clearness and simplicity. The book should find a valuable field as a textbook in this country as well as in Great Britain.

The Work of Our Hands. By HERBERT J. HALL, M. D., and MERTICE M. C. BUCK. New York: Moffat, Yard & Co. 1915.

This volume, published as a study of occupations for invalids, is based on the experience of the authors who, for several years, have devoted special attention to the development of modified work in the treatment of nervous disability and as an aid for the self-support of the blind, crippled and infirm. The book is divided into two parts. The first, by Dr. Hall, represents his work in his sanatorium at Marblehead, Mass., the second, by Miss Buck, deals with her experience in charitable institutions of New York City. Much of Dr. Hall's material has previously appeared in columns of this JOURNAL and of the *Journal of the American Medical Association*. The book is illustrated with eight full page plates. At its conclusion is an appendix in which are tabulated the varieties of occupation employed in the industrial department of the Massachusetts State Colony for the Insane at Gardner. There is also a tabular statement of the agricultural farm products, with appended values, at the several cottages of this institution. The work presents numerous evidences of what may be accomplished with patience and persist-

ence in the use of the work treatment and the value of this treatment is evidenced by the results obtained.

The Practitioner's Encyclopedia of Medical Treatment. Edited by W. LANGDON BROWN, M. D., F. R. C. P., and J. KEOGH MURPHY, M. C., F. R. C. S., London: Henry Frowde and Hodder and Stoughton 1915.

This encyclopedic volume, dedicated to Sir William Osler and Sir Clifford Albutt, consists of a series of non-alphabetic monographs by distinguished British experts on various aspects of therapeutics. It is divided into two parts, the first being concerned with methods, the second with agencies in treatment. The subjects are logically arranged, being grouped according to the natural and systemic nosologic categories. In his introduction Sir Clifford Albutt sketches the history and rationale of therapeutics. The volume is well printed but without illustrations. It concludes with an appendix of notable alterations in potency and nomenclature and notable additions of organic chemicals in the British pharmacopoeia of 1914. There is an extensive and convenient index.

The Principles of Human Physiology. New (2nd) edition. By ERNEST H. STARLING, M. D., F. R. C. P., F. R. S., Jodrell Professor of Physiology in University College, London. Octavo. pp. 1271. With 566 illustrations, including 10 in colors. New York and Philadelphia: Lea & Febiger. 1915.

The second edition of this excellent work is chiefly noteworthy for its very satisfactory presentation of the energetics of muscular activity. Its discussion of nervous conduction is in accord with the most recent discoveries in that field. In general, such minor changes have been made as are necessary to keep the book abreast of the rapid progress that is now being made in physiology. Unfortunately, in his discussion of the suprarenal bodies and of adrenin, the author has failed to take into account the recent very enlightening observations concerning the emergency function of adrenin. The older point of view, which emphasizes the rise in blood pressure induced by this hormone, places an incidental function so much in the foreground that the truly remarkable significance of the mechanism escapes the student entirely. To be sure, much of this work is so recent that it may not have been possible to include it in this book. The necessity of issuing frequent editions of expensive textbooks is to be regretted but probably cannot be avoided in sciences that are advancing as rapidly as is physiology.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, DECEMBER 2, 1915

EDITORS.

CHRISTIAN SCIENCE A CHAMPION OF RADICAL SURGERY.

In the last days of the late Mrs. Eddy it was said that she relaxed her earlier principles sufficiently to permit of her followers making use of surgery under certain conditions, as, for instance, "belief in" a broken bone. It was even reported that the founder herself entertained a suspicion of, if not a belief in, toothache, for which she resorted to the dentist instead of trusting solely in God. So that there are said to be at the present time certain "Christian Science dentists," who treat an exposed nerve not alone by the pure Truths of the Spirit but by the addition of cold steel as well.

Still, operative surgery does not seem to be a part of the teachings of "Science and Health," and few of us expected to see the day when the official organ of that cult would take the medical profession to task for lukewarmness in zeal for bloody surgical operations. Yet this

is just what happens in the leading editorial in *The Christian Science Monitor* of November 19, of which marked copies have been sent to many physicians by the management.

The case is that of the too much talked of Chicago monstrosity, which a surgeon simply decided to let alone. A blind, deaf and deformed monster had, in addition, as we understand it, an intestinal occlusion of a nature which in a normal infant would have demanded a surgical operation in hope of removing the obstruction (unless, indeed, "Science" could have promptly stepped into the breach and established normal function).

The question of an active euthanasia was never raised as to this unfortunate child. That is an entirely different issue, regarding which medical men are divided, but as to which the prevalent opinion is still doubtless adverse. A passive or permissive euthanasia seems to have commended itself to the surgeon in charge and also to the mother of the child. Hence the infant was simply let alone, and Nature, which in her inscrutable mystery had sent the child into the world lacking most of its faculties, was allowed through the intestinal obstruction, which was one of the chapters in the pathologic history, to take away the life she had sent.

Yet the *Monitor* says that the doctor "broke the law." "He permitted the baby in this case to die."

Where else in the world can we find such sublime confidence in the omnipotence of the surgical art as in this assumption that an operation, which the doctor is so savagely scored for omitting, would have certainly saved the child's life! Many a medical man has less confidence. Let us quote:—

"The claim of a Chicago doctor to the right to destroy human life for medical reasons brings the whole question of medical autocracy into the strongest light. . . . So long as any medical man is content with campaigns for pasting red crosses on the shoe toes of children, he is merely humorous. When he goes further and proposes tuberculosis weeks, or takes children down to malaria swamps to fill their minds with the dangers of mosquito poisoning, he becomes dangerous, inasmuch as he instills into the human consciousness a dread of the very disease which he professes later to attempt to eradicate from a body that consciousness has developed. When, however, he claims the right to decide whether a patient is to live or die, he involves himself in what we assume orthodoxy would term blasphemy, the law courts illegality, and the ethical standards criminality. Years ago the legislative bodies of the world took up arms against what

is known as baby farming. Baby farming had become a process for expediting infant mortality, and we see no reason whatever for supposing that the immorality, which found vent for its ingenuity in baby farming, cannot again find room for the same ingenuity in a process of diagnostic removal."

The Chicago surgeon seems to have been guilty in this case at the same time both of withholding the knife and of making a "diagnostic removal," a feat which was to be expected of the ingenuity which caused the medical profession to make that well-known invention of theirs, the baby farm, to expedite infant mortality.

To the order of minds which are tickled with the "humorousness" of Red Cross work, such an expedition as checked the ravages of typhus in Serbia may well appear a frolicsome farce. The "dread" of typhus killed 150,000 Serbians before it was dispelled. Yet malaria and tuberculosis have as little foundation, and not only are all these merely a state of fear, but these people now speak even of the human "body that consciousness has developed."

The former shibboleths seem to stand fast, but what shall we say when told that a surgeon who refuses to operate has done what "orthodoxy would term blasphemy, the law courts illegality and the ethical standards criminality"?

CHARLES F. WITHERINGTON.

FOOD-DEFICIENCY DISEASES.

THE study of physiological chemistry and the metabolic processes of the body has focussed a new interest on the part that the individual food elements play in the body processes. Perhaps the condition known the longest to be caused by the deprivation of some food element, with resulting metabolic disturbances characterized with definite symptomology, is scurvy. Even long ago when the nature of the condition was not understood, and the disease very prevalent on ships long away from port or in other places where fresh food supplies were not accessible, it was yet known that the addition to the dietary of fresh food was curative. The disease is now very rare, mainly due to the improvements in transportation wherein ships are not so long away from the possibilities of fresh larder. However, when it does occur, as happened very recently in a sea raider, the disease bobs up with the same character and severity as in years by gone. Fresh vegetables, fresh meat and lime salts and lime juices are the elements

of food that are both curative and prophylactic against scurvy. In bottle-fed babies, scorbutus remains a definite and recognized disease, occurring not infrequently as a result of feeding exclusively with cooked milk, and from the consequent deficiency of citrates in the diet.

The range of food-deficiency includes, beside, rickets, tetany, or allied polyneuritic conditions, beri-beri, pellagra, and perhaps also diabetes.

Rickets is caused mainly by faulty feeding in children. The long administration of boiled milk seems to predispose. The boiling appears to destroy some enzyme necessary in metabolism. Rachitis is further associated with an excess of carbohydrates over proteins in the diet, and is dependent on the consequent deficiency of calcium salts. It is peculiar, however, that the disease does not develop much after two years of age. It is notoriously common where environmental conditions are very bad.

Much study has been expended on the nature of beri-beri because it represents a disease of great prevalence and fatality in the Orient. The one-sidedness in food consumption of those peoples has long been suspected as the causative factor. They subsist almost entirely on rice, and for some reason polish it: that is, they remove the shell. It has been found that where the rice is consumed whole, beri-beri will not develop. In fact, so well is this now established that in the Philippines, under Heiser, a tax of some magnitude has been placed on rice polishings to prevent this. The feeding of rice polishings to those suffering from beri-beri was found to cure them. Or, those subsisting on polished rice, who would add to their diet separately a quantity of rice polishings, would not contract the disease. The element removed with the polishings is believed to be a sulphur compound, and it is this deprivation which causes the nervous symptoms so characteristic of this disease.

Recent investigations by Goldberger* of the Hygienic Laboratory have perhaps fully confirmed the previous well founded suspicion that pellagra is due to a food-deficiency. His experiments on a prison colony of about eighty in which eleven volunteered for the experiment of being fed on a one-sided diet, while the rest acted as controls, are classic. Within five months six out of the eleven developed undoubted cases of pellagra. It is a one-sided diet of cereal carbohydrate that seems to be at the bottom of this condition. A summary of the

* Weekly report United States Public Health Service, Nov. 12, 1915.

experiments by Dr. Goldberger and Dr. Wheeler is published in another column of this issue of the JOURNAL (page 862).

No certainty in food etiology has yet been found in the causation of diabetes, though the trend of present investigation is in that direction.

In nearly all of these cases of food-deficiency it seems that it is the lack of proteins that stands out prominently. The food element lacking in these conditions has been named a vitamin. There are both proteid and carbohydrate vitamins—both necessary for normal metabolism. All of these vitamins are different according as they are of animal or of vegetable extraction. Human beings are omnivorous and need both animal and vegetable food. In any event it is rather the kind of food—the variety and quality—than the quantity which is the determining factor in metabolism. There is much more real starvation in a gluttony with food of one variety than in the ingestion of a minimum quantity of a mixed food. Starvation cannot be induced by minimum quantity as long as there is maximum variety. Indeed, a small quantity of mixed foods is more satisfying to the appetite than a large quantity of a single kind.

CHILD LABOR LEGISLATION.

THE Children's Bureau of the Department of Labor now reports that forty-five states have passed child welfare laws. It will be remembered, however, that Congress itself defeated a bill recently which purposed to control indirectly child labor by prohibiting the passage in interstate commerce of articles manufactured in canneries, mills or factories by children under fourteen years of age. Clearly the abolition of child labor, no matter in what form accomplished, would seem to be most commendable legislation. It is a step in the direction of progress—a step in the conservation of health and life. The confinement necessarily entailed in these industries and the devoting of energies to other purposes than to the child's own physical and mental development, are a handicap that cannot be easily overcome in later years.

Nevertheless, this obstacle to human progress will not be removed by such an evasion of the real issue as is represented by the contemplated federal law, or as was previously proposed by Senator Beveridge of Indiana, who urged that

articles manufactured by children shall not be considered as legitimate articles of commerce, and thus their transportation prohibited. Clearly the remedy lies either in the uncertain method of having each state make its own varied restrictions of child labor, or in so enlarging the legitimate health powers of the federal government that it can directly control this palpable menace to health. It is during the most rapid growth and development of childhood that the very slightest obstruction tends to permanent disorganization of these processes.

In the same class with child labor legislation, and bearing on it indirectly in respect to child welfare, is legislation controlling the hours of labor and the kind of labor of women. The federal court upheld the right of the state to regulate the hours of labor in certain occupations when it laid down the rule that "the right to regulate or control persons in any trade or occupation that affects the health of the people in general is no longer an open question." Yet it demurred at making special exemptions in favor of women and against woman labor. Labor of the kind prohibited in the child labor legislation cannot fail to have a bad effect on the actual or the potential mother, on her offspring, and in this way on the people in general. Indeed, in the investigation by David Heron of the Yorkshire, England, woolen mills, he found that mothers' labor had a worse effect on the child and on the community than child labor. For, prior to the prohibitive legislation against child labor, the families were large—the children were assets who were well looked after; and since this legislation, prenatal destruction of child life is common, because childbearing is a drawback to efficiency; and children born show the ill effects of maternal pressure and fatigue. Obviously there is little or no choice between these two evils. The remedy lies only in legislative hand in hand for both conditions.

SWIMMING-POOL SANITATION.

WITH the growth in popularity of swimming as an amusement and with its increasing appreciation as an aid to health and safety there comes the danger of the dissemination of disease through the medium of the municipal swimming pool. At present in this country 99 large cities have public swimming pools, and how many more cities and towns have something of the kind we

have no means of knowing. Care of these pools naturally varies from the most scrupulous to the most indifferent. Even among those where the method of care is intended to be the best possible the ideas of effectual sanitation vary so much that it does not seem probable that they can all be correct.

With the purpose of ascertaining what methods were in current use, Dr. Manheimer recently investigated forty-six municipal and other pools in large cities and published his results.* He describes the methods of cleansing used in six different pools as typical of all. The methods in use were, broadly speaking, mechanical, chemical, by refiltration, or by combinations of two or more of these methods. The best method of all he states to be refiltration plus chemical purification, the preferred chemical to use being chloride of lime in the proportion of one of chloride to one million of water. He especially emphasizes that pools should be large enough, frequently diluted, carefully supervised and often refiltered.

The principal diseases spread by means of the community swimming pool are venereal diseases and typhoid fever. It may be easily understood theoretically how syphilis and gonorrhea can be distributed by such a medium as the public bath, but typhoid fever does not at first glance seem such a probable menace. The studies of Rosenau, Lumsden and Kastle have shown that three-tenths per cent. of people are typhoid carriers. That is, in a city the size of New York there must be about 15,000 typhoid carriers. Or, to present it in another way, supposing that we have a swimming pool which about 300 persons use each day, the probability is that one of these bathers is a typhoid carrier. These facts alone, aside from the esthetic satisfaction which must accompany the use of a swimming pool which is known to be kept clean, are sufficient to impress upon the physician who has the health of the community at heart the necessity of the most approved methods of sanitation of such places.

* Essentials of Swimming-Pool Sanitation. By Wallace A. Manheimer, Ph.D., U. S. Public Health Reports, Sept. 17, 1915.

THE WORK OF A SPECIAL SURGICAL DEPARTMENT.

In another column of this week's issue of the JOURNAL we are glad to republish from the Har-

vard Medical Bulletin of May, 1915, a brief article by Dr. Paul Thorndike of Boston, discussing the general subject of surgical specialties in hospitals, particularly as illustrated by the organization and work of the recently organized urological service at the Boston City Hospital. The success which this service has attained during the two years of its existence gives additional interest and importance to the subject and to the writer's comment.

The problem of establishing special surgical services in large general hospitals is always difficult on account of the inevitable and natural feeling on the part of general surgeons that such a procedure takes from them opportunity which is legitimately theirs. At the same time it is imperative that such services should be established on account of the best interests of the patients, of medical education and of those surgeons who are devoting their time and energy to the acquirement of expert skill in special branches of surgery.

The method adopted at the Boston City Hospital for the reconciliation of these conflicting interests and necessities seems largely to have solved this problem. By an equitable division of cases, it secures all the advantages of a special service without infringing on the rights and interests of other members of the hospital staff. In point of fact its success has been particularly marked in the efficiency already developed by the new urological service at that institution. In practice, if not in theory, it would seem that this method might well be adopted, if indeed it has not already been so, in other departments of the City Hospital and in other institutions.

MEDICAL NOTES.

PREVALENCE OF MALARIA, MENINGITIS, PLAGUE, POLIOMYELITIS, SMALLPOX, TYPHOID AND YELLOW FEVERS.—The weekly report of the United States Public Health Service for November 12 states that during the first quarter of 1915, 2359 cases of malaria were reported in Arkansas. During the week ended October 23 there were 35 cases of cerebrospinal meningitis in Elizabeth, N. J., and seven cases of poliomyelitis in Cleveland, Ohio. A fatal case of plague occurred in Hawaii on October 30. During the week ended November 6 four new foci of smallpox infection were reported in Minnesota, the number of cases being few. During the week ended October 23 there were 126 cases of ty-

phoid fever in New York City and 45 in Baltimore. A case of yellow fever arrived at Balboa, Canal Zone, on October 25, aboard the steamship *Jamaica*, from Buena Ventura, Columbia.

HOSPITAL GIFT.—It is announced that Mrs. Isaac L. Rice of New York City has given to the Beth Israel Hospital of New York the sum of \$1,000,000 for the establishment in that city of a hospital, to be known as the Isaac L. Rice Hospital for convalescents. This new hospital is not to be a part of the older institution but will be under the administration of the Beth Israel Hospital Association.

NEW YORK HEALTH DEPARTMENT'S LOW 1915 DEATH RATES.—Dr. Guilfoyle of the New York Department of Health reports that there were 1324 deaths during the past week with a rate of 12.34 per one thousand of population, against that of 1276 deaths in the corresponding week in 1914, an increase in the absolute number of deaths of 48, and an increase in the rate per 1000 of the population of .2 of a point.

The most noteworthy features of the mortality during the week were the decrease in the number of deaths reported from the acute infectious diseases, and the increase in the deaths reported from the diarrheal and respiratory diseases. The mortality from organic heart disease and pulmonary tuberculosis remains approximately the same. The mortality of children under one year of age was considerably above that of last year, the total reaching 232 as against 183, an increase of 49 deaths. Between one and five years of age the mortality was slightly lessened. At the other age groups approximately the same number of deaths were reported.

The death rate for the first 46 weeks of the year 1915, based upon a revised estimate of the population, was 13.59 per one thousand of population as against a rate of 13.75 per one thousand of the corresponding period of 1914, a decrease in the mortality of .16 of a point. If this decrease be maintained during the remaining weeks of the year there will be approximately 885 fewer deaths than in the year 1914.

EUROPEAN WAR NOTES.

CHOLERA IN AUSTRO-HUNGARY AND GERMANY.—During the week ended September 25, 1915, there were among civilians in Germany, two cases of Asiatic cholera each at Thorn, Tilsit and Prettow. Other cases occurred among soldiers in prison camps at Allenstein, Cassel, Marienwerder, Oppeln, Posen and Stettin.

SECOND MEDICAL EXPEDITION TO GERMANY.

On Nov. 25 there sailed from New York City aboard the *Hellig Olav* for Copenhagen, the second medical expedition to Germany under the auspices of the German relief committee of New York. The personnel consists of Dr. Fred Kammerer, Dr. Kurt Sauer, Dr. Frank D. Gorham,

and six nurses. Supplies were carried for a hospital of 400 beds.

AMERICAN SURGEONS IN USKUB.—Report from Saloniki, Greece, on Nov. 17, by way of Paris on Nov. 23, states that at the recent capture of Uskub, Serbia, by the victorious Bulgars, five American Red Cross surgeons remained in that city. They are Dr. Stanley S. Osborne, of Peabody, Mass.; Dr. Charles E. Fox, of Baltimore; Dr. Harry Plotz, of New York; Dr. George Bahr, of Brooklyn; and Dr. A. F. Cornelius, of Berea, Ky. It is understood that negotiations are in progress, through the American and Bulgarian consulates, to secure their release.

WAR RELIEF FUNDS.—On Nov. 27 the totals of the principal New England relief funds for the European War reached the following amounts:

Belgian Fund	\$288,094.04
Red Cross Fund	142,177.51
American Ambulance	70,565.58
Polish Fund	56,258.11
Serbian Fund	50,602.60
Allied Fund	38,453.30
British Fund	38,048.56
French Fund	25,440.66
Armenian Fund	16,939.63
LaFayette Fund	12,382.99
Italian Fund	12,101.69
Surgical Dressings Fund	11,085.50
St. John's Ambulance	392.00

BOSTON AND NEW ENGLAND.

THE WEEK'S DEATH RATE IN BOSTON.—During the week ending Nov. 27 there were 210 deaths reported, with a rate of 15.04 per 1,000 population as compared with 22 and a rate of 16.08 for the corresponding week of last year.

There were 30 deaths under 1 year as compared with 29 last year, and 68 deaths over 60 years of age against 71 last year.

Total deaths reported in 47 weeks from Jan. 2 to Nov. 27 were 10,621 against 10,645 for the corresponding period in 1914.

Deaths under 1 year reported in the same period were 1812 against 1804 for the corresponding period in 1914.

In Boston in 1914 per 1000 births of mothers born in the United States there were 120 deaths under 1 year; while the rate for children of mothers born in Canada was 107; for those of Irish mothers, 101; for those of Italian mothers, 88; and for those of Russian and Polish mothers, 78.

Similar findings for New York City based upon official figures have been published recently. In a word, if a baby wishes to survive it should choose a foreign-born mother.

DEDICATION OF ST. ELIZABETH'S HOSPITAL.—On Sunday, Nov. 21, the new buildings of St. Elizabeth's Hospital, Brighton, were formally dedicated with fitting ceremonies. Although the

hospital was opened on Aug. 31, 1914, the death of Pope Pius X had made it necessary to postpone the dedicatory exercises until the present time. Low mass was celebrated in the chapel, followed by an address by Cardinal O'Connell and an official inspection of the hospital buildings.

A RULING ON INSOLATION. On November 19, the State Industrial Accident Board rendered a decision at Quincy, Mass., that a sunstroke received during the performance of work does not constitute a claim under the Workmen's Compensation act. The ruling was made in a case in which the Board found that the insolation was not caused by anything unusual in the character of the work and that it did not arise out of or in consequence of the employment.

ESTABLISHMENT OF QUIET ZONES.—The subject of quiet zones about hospitals has been discussed in the JOURNAL from time to time in the past. On Monday of last week, November 22, the Boston City Council unanimously passed an ordinance providing for the establishment of such zones in this city. The ordinance requires that automobiles and horse-drawn vehicles shall run slowly and with a minimum of noise within one hundred yards of all hospitals. Venders and other persons are also warned not to make undue noise, and the use of musical instruments is prohibited within these zones.

DANVERS PATHOLOGIC CONFERENCE.—On November 19 there was held at the Danvers State Hospital a conference in commemoration of the twentieth anniversary of the foundation of the pathologic laboratory at that institution, the first laboratory of its sort to be established in a hospital for the insane in Massachusetts. About seventy physicians were in attendance at the conference, and among the guests were Dr. Arthur H. Harrington, superintendent of the Rhode Island State Hospital, and Dr. Charles W. Page. At the afternoon session a series of papers was presented by the following physicians: Dr. Henry M. Adler, Harvard; Dr. James Ayer, Harvard; Dr. Henry A. Cotton of the State Hospital, Trenton, N. J.; Dr. E. E. Southard, Dr. M. M. Canavan, Dr. James J. Putnam, Dr. Page, Dr. Harrington, Dr. Sanger Brown, Dr. S. P. Kramer of Cincinnati, and Dr. L. G. Lowery, pathologist at Danvers.

NEW ENGLAND PEABODY HOME.—The annual meeting of the New England Peabody Home for Crippled and Deformed Children was held in Boston on November 15. Dr. Robert Soutter reported particularly on the value of the sun treatment for surgical tuberculosis. The following staff was appointed for the ensuing year: surgeons, Dr. Robert W. Lovett, Dr. Robert Soutter and Dr. Edwin Fiske; attending physician, Dr. Clarence Bryant; advisory board, Dr. Abner Post and Dr. Edward B. Kellogg.

SOCIAL SERVICE ANNIVERSARY.—The tenth anniversary meeting of the Social Service Department of the Massachusetts General Hospital was held in Boston on Nov. 30 under the presidency of Dr. Richard C. Cabot. The principal address was by Mr. Homer Folks, secretary of the State Charities Aid Association of New York, on "Humanizing the Institution."

MENTAL HYGIENE CONFERENCE.—Dr. A. J. Rosanoff of Kings Park State Hospital, New York, in addressing the Mental Hygiene Conference held recently in this city, stated that 22 per cent. of the male patients admitted to the New York state insane hospitals in 1913 owed their disability to the immoderate use of alcohol. A large number of patients, although predisposed to insanity, probably would have escaped its development had they not been intemperate. Dr. Irwin H. Neff of the Norfolk State Hospital discussed the rational care of inebriates. Dr. Henry P. Frost of the Boston State Hospital discussed the need of assistance and supervision of patients discharged from insane hospitals, and Dr. John B. MacDonald spoke of the usefulness of the newly established out-patient department of the hospital. He reported that during the months of July, August and September, over 1200 persons visited the clinic and 2850 visits were made by the social workers connected with the department to patients on parole under the care of the hospital, and to persons in the community who, of their own volition, sought advice and assistance. Professor W. H. Burnham of Clark University urged a thorough medical and mental inspection of all school children in order that mental and physical defects might be checked and controlled before they become fixed habits.

BOSTON ASSOCIATION FOR THE RELIEF AND CONTROL OF TUBERCULOSIS.—The twelfth annual meeting of the Boston Association for the Relief and Control of Tuberculosis was held in this city on Monday of last week, November 29. Following the regular business there were addresses by Miss Ella Phillips Crandall, R.N., executive secretary National Public Health Nurses' Association, New York City, on "The Tuberculosis Nurse as a Modern Health Agent"; and Miss Eunice H. Dyke, R.N., superintendent of Nurses' Department of Public Health, Toronto, Canada, on "Generalized Nursing in Toronto."

DISTRICT HEALTH OFFICERS.—The State Department of Health has accepted the resignation of Dr. W. H. Coon, of Haverhill, Mass., appointed district health officer, who is to become medical supervisor of a large manufacturing plant. To fill the vacancy, Dr. Lyman A. Jones of North Adams will be transferred from the Berkshire District to Haverhill and a new health officer will be appointed to take charge of the Berkshire District. It is hoped that Dr. Stanley

S. Osborne, a member of the American Red Cross Sanitary Commission of Serbia and now captured by the Bulgarians, may be reached and the appointment given to him.

REPORT OF THE FAULKNER HOSPITAL.—The eleventh annual report of the Faulkner Hospital of Jamaica Plain, Mass., for the year ending May 1, 1915, states that the most notable feature of the work of the hospital has been the growing demand for maternity service. There have been accommodated during the past year forty-nine cases in contrast to nine cases of five years ago, and many have been turned away. The trustees, realizing the urgent need of a separate building in which to care for such cases, have appointed a committee to consider the question of erecting a separate maternity building. The total number of patients treated during the year was 635.

LECTURE BY DR. STRONG.—On Monday of last week, November 22, Dr. Richard P. Strong, professor of tropical medicine in Harvard University, gave an illustrated lecture in Sleeper Hall, Boston, on Serbia and the suppression of typhus fever. This lecture was given for the benefit of the Social Service Department of the Massachusetts General Hospital and described Dr. Strong's experience as chief of the American Red Cross Typhus Commission last summer.

MUNICIPAL HEALTH UNITS.—It is announced that, with the approval of Mayor Curley, Dr. Francis X. Mahoney, Boston Health Commissioner, will establish in the Ward and Municipal Building on Blossom Street, a trial health unit, being a headquarters station for the district health inspectors and nurses. This project has been endorsed by the Boston Instructive District Nursing Association and the Boston Milk and Baby Hygiene Association. If it proves successful, it is planned to establish similar permanent units in other sections of the city.

Massachusetts Medical Society.

PLYMOUTH DISTRICT MEDICAL SOCIETY.—On Tuesday of last week, November 23, the Plymouth District Medical Society held a meeting and dinner at Brockton, Mass., in recognition of the work of five local physicians, each of whom has been engaged in practice for at least fifty years. These five men are Dr. A. Elliot Paine of Brockton, Dr. Calvin Pratt of Bridgewater, Dr. Edward Cowles of Plymouth, Dr. Horatio F. Copeland of Whitman, and Dr. Samuel H. Durgin of Duxbury. All are veterans of the Civil War. The dinner, which was highly successful, was attended by about seventy members of the society.

Obituary.

GEORGE EDWIN PINKHAM, M.D.

DR. GEORGE EDWIN PINKHAM, a retired Fellow of the Massachusetts Medical Society, died at his home in Lowell, November 15, 1915, aged 75 years.

Dr. Pinkham was born in Lowell in 1840. He received his early education at the Dover High School and Franklin Academy, Dover. After pursuing a course of study at the Harvard Medical School, he entered Dartmouth Medical School, and graduated from there with the degree of M.D. In 1862 Dr. Pinkham went to Lowell for the purpose of studying, but at the outbreak of the Civil War he enlisted in the famous Sixth Massachusetts Regiment, and served throughout the war in the capacity of assistant surgeon. When the army was disbanded, Dr. Pinkham returned to Lowell and settled permanently in that city, where he pursued his chosen calling until illness incapacitated him.

He was commandant of Post 185, G.A.R., and was at one time medical director of the first brigade of Massachusetts Volunteers for seven years. In 1866 he was a member of the Lowell council, alderman in 1877, member of school committee during the years 1870, 1874 and 1875, 1880 and 1881, city physician from 1866 to 1868. He was president of the Middlesex North Medical Society for two years, and since 1862 had been a member of the Massachusetts Medical Society. He is survived by his widow.

Miscellany.

EXPERIMENTAL INVESTIGATION OF THE CAUSE OF PELLAGRA.

THE United States Public Health Service has recently issued a bulletin describing the progress of the experimental investigation which it has been making, with a view to determining, if possible, the cause and the cure of pellagra. As a result of this research it is suggested that pellagra is, in reality, a deficiency disease, analogous to beri-beri and scorbutus, caused probably by insufficiency of proteid diet. The statement issued by the department is in part as follows:

"Pellagra has been increasing alarmingly throughout the United States during the last eight years, and it is estimated that 75,000 cases of the disease will have occurred in the United States in 1915, and of this number at least 7500 will have died before the end of the year. In many sections only tuberculosis and pneumonia exceed it as a cause of death.

The most recent experiment of the Public Health Service was carried out at the farm of the Mississippi State Penitentiary about eight miles east of Jackson, Miss., and together with the previous work of the Service, completes the chain in the prevention and cure of the disease. The work at the Mississippi Farm has been in charge of Surgeon Joseph Goldberger and Assistant Surgeon G. A. Wheeler of the United States Public Health Service. The Farm consists of 3200 acres, in the center of which is the convict camp. The final experiment was undertaken for the purpose of testing the possibility of producing pellagra in healthy human white adult males by a restricted, one-sided, mainly carbohydrate (cereal) diet. Of eleven convicts who volunteered for this experiment, six developed a typical dermatitis and mild nervous gastro-intestinal symptoms.

Experts, including Dr. E. H. Galloway, the secretary of the Mississippi State Board of Health; Dr. Nolan Stewart, formerly superintendent of the Mississippi State Hospital for the Insane at Jackson; Dr. Marcus Hause, professor of dermatology, Medical College of the University of Tennessee, Memphis, Tenn.; and Dr. Martin R. Engman, professor of dermatology in the Washington Medical School, St. Louis, Mo., declare that the disease which was produced was true pellagra.

Prior to the commencement of these experiments, no history could be found of the occurrence of pellagra on the penitentiary farm. On this farm are 75 or 80 convicts. Governor Earl Brewer offered to pardon twelve of the convicts who would volunteer for the experiment. They were assured that they would receive proper care throughout the experiment, and treatment should it be necessary. The diet given was bountiful and more than sufficient to sustain life. It differed from that given the other convicts merely in the absence of meats, milk, eggs, beans, peas, and similar proteid foods. In every other particular the convicts selected for the experiment were treated exactly as were the remaining convicts. They had the same routine work and discipline, the same periods of recreation and the same water to drink. Their quarters were better than those of the other convicts. The diet given them consisted of biscuits, fried mush, grits and brown gravy, syrup, corn bread, cabbage, sweet potatoes, rice, collards, and coffee with sugar. All components of the dietary were of the best quality and were properly cooked. As a preliminary, and to determine if the convicts were afflicted with any other disease, they were kept under observation from February 4 to April 9, two and a half months, on which date the one-sided diet was begun.

Although the occurrence of nervous symptoms and gastro-intestinal disturbances was noted early, it was not until September 12, or about five months after the beginning of the restricted diet, that the skin symptoms so characteristic of pellagra began to develop. These symptoms are

considered as typical, every precaution being taken to make sure that they were not caused by any other disease. The convicts upon whom the experiment was being made, as well as twenty other convicts who were selected as controls, were kept under continuous medical surveillance. No cases of pellagra developed in camp excepting among those men who were on the restricted diet. The experimenters have therefore drawn the conclusion that pellagra has been caused in at least six of the eleven volunteers as a result of the one-sided diet on which they subsisted."

Subsequent confirmation of these results by other experiments may lead to the complete demonstration of the suggested etiology. Such confirmation must, of course, be awaited before the unqualified acceptance of these conclusions.

STATUS OF ENGLISH MEDICAL STUDENTS.

IN the issue of the *London Times* for August 25 attention was called by the medical correspondent of that periodical to the danger of the announcement that the British War Office "would be very unwilling to suggest that junior medical students should be discouraged from taking combatant commissions." In its issue of November 3 the *Times* reverts to the same topic with particular reference to the status of medical students since the publication of Lord Derby's recent appeal to the male population. Its comment on this important question is in part, as follows:

"The War Office was willing that medical students in their fourth and fifth years should continue their studies with a view to qualifying as soon as possible, and discouraged the granting of commissions to these men, but the medical profession urged that by allowing the younger students to take combatant commissions the visible supply of medical students would be used up, and the medical schools emptied, so that three or four years hence the number of doctors would be even lower than at present.

"In view of the recent issue of Lord Derby's appeal, which was received by the junior students at the medical schools, the question has again come to the front, and yesterday a deputation consisting of the President of the College of Physicians, the President of the College of Surgeons, the Deans of the medical schools, and the Vice-Chancellor of the University of London waited upon Lord Derby to discuss the matter with him. It was pointed out to him that the medical curriculum extends to five years, and in view of the fact that Lord Derby's letter was being received by students in their first, second, and third year the authorities were anxious to know whether it would not be possible to

exempt them. It was urged very strongly that the medical student would be of much more service to the nation if he continued his studies and qualified as a doctor in three, four, or five years' time than if he joined the Army as a combatant at present.

"Lord Derby, after hearing the views of the deputation, gave his decision on the point in the following words: 'It is the duty of medical students (other than those in the fourth and fifth years of study) to join His Majesty's Forces.'

"According to the statistics published at the beginning of September, the number of students in 10 leading medical schools during the first year of the war was 1891, as compared with the normal total of 2562. The effect of Lord Derby's decision will be, of course, to deplete the number of students still further.

"In his presidential address at the opening of the 102nd session of the General Medical Council recently, Sir Donald MacAlister dealt with the question of recruiting medical students.

"They had it on the highest authority, he said, that within the next few months every qualified man of suitable age who was fit for the work of an officer in the medical corps would be needed. The profession looked to the public to lighten the sacrifices and burdens which all practitioners must endure in these days both by loyalty to the absent and by consideration for those who took their place. The proportion of country practitioners who had been set free for military service was higher than that from the large centres of population. The town doctor, owing to the somewhat loose attachment of his patients to him, feared that they might be alienated if he went into the Army. The Medical War Committees were endeavouring to promote equitable agreements between practitioners who remained on civil duty and their colleagues on active service, and he thought the profession had given abundant proofs that it would not be wanting in duty or in self-denial.

"From the British Dominions and from other countries over 240 practitioners had been registered this year, and it was believed that when certain reciprocity arrangements had been completed, the number from Canada would be considerably increased. Although the War Office authorities recognized that the withdrawal from professional instruction of large numbers of medical students, of the first three years, would have a serious effect on the future, they had deemed it inadvisable to discourage junior students who offered themselves for combatant service. It was much to be desired, he thought, that the Army authorities should give clearer guidance on this perplexing question. The result of medical students accepting commissions and enlisting was that the prospective shortage of 250 qualified practitioners per annum which he had mentioned on a former occasion as probable during the coming years would almost certainly be exceeded."

MEMORIAL OF DR. AUSTIN FLINT.

At its meeting on October 15, 1915, the medical faculty of Cornell University adopted the following memorial of the late Dr. Austin Flint, whose obituary notice appeared in the issue of the JOURNAL for October 7:

"Austin Flint, M.D. LL.D., professor emeritus in the Cornell University Medical College, passed away September 22, 1915, in the eightieth year of his age. A student of Claude Bernard and of Robin, he early achieved distinction. Thus, in 1862, at the age of twenty-five, he discovered a substance in human feces which he called *stereorin*, recognizing it as a derivative of *cholesterin*. This discovery was awarded honorable mention by the Institute of France. It did not receive full recognition because of an unfavorable pronouncement by Hoppe-Seyler. However, in 1896, *stereorin* was again discovered, this time by Bondzynski, and given the name of *koprosterin*. To Flint, however, working with older, cruder methods, belongs the credit of having first isolated the substance in pure crystalline form. Austin Flint was one of the greatest teachers of the old school of American medicine. A forceful orator and skilled experimentalist, he was the first in this country to expound the doctrines of the French school of physiology which in his early life was at the height of its renown. Dr. Flint took pride in being of the fifth generation of noted physicians, his great-grandfather and his father having borne the name Austin Flint, a name which outlives him in a surviving son.

RESOLUTIONS.

ADOPTED by The American Medical Editors' Association, at its recent meeting in New York.

Whereas, The American Medical Editors' Association believe that the principle of the freedom of the press bears unusual force in relation to the medical press, discussing subjects germane to medical progress, and

Whereas, *The Southern California Practitioner* has been indicted by the United States Postal Department because of the publication of an article dealing with the "sex question" which appeared in the issue of March, 1914.

Be It Resolved, That the American Medical Editors' Association express to Dr. George E. Malsbary, Editor of the *Southern California Practitioner*, its confidence and moral support in the pending action.

Be It Resolved, That the American Medical Editors' Association assure Dr. Malsbary of its willingness and readiness to afford him any assistance and support within its power according to the Constitution and By-Laws.

IRA S. WILE,

C. W. FASSETT,

HENRY R. HARROWER,

Committee.

October 19, 1915.

Correspondence.

AN AUTHOR'S CORRECTION.

BOSTON, MASS., NOV. 22, 1915.

Mr. Editor: An editorial comment in the JOURNAL for Nov. 18, regarding an article of mine on the "Midwife Problem" appearing in the same number, states that the article in question "reaches the conclusion that in view of the obvious deficiencies of training in obstetrics in this country, the best method of meeting the needs of the situation is to adopt the midwife system of Europe, placing it, however, under suitable regulation and providing adequate training for those who undertake this work." I would take exception to this as not being a correct statement of the conclusions reached. I recognize the right of the editor to differ with or to criticize opinions expressed in the article, but not to base those differences or criticisms on a misinterpretation.

The article, attempting to deal with the subject broadly, describes the opinions of many workers in this field, and while those opinions may not always be our own, at least, they merit our respectful consideration. In conclusion, it states: "There is a distinct tendency in many quarters to adopt the midwife as an institution after the manner of its conduct in the countries of Europe," a statement of fact, not an opinion that it is the best solution of the problem. Further, the article even questions if it is the most practical solution, as is shown by the conclusion that "our method of government is not adapted to the rigid requirements which the properly regulated midwife demands."

My suggestion for securing for "every parturient the attention commensurate with present-day standards" is not by the establishment of a midwife organization, but rather that the community, coming to realize its vital interest in this problem, adopts the care of its maternity cases in the same manner that it adopts the care of those of its sick who are unable to secure proper care for themselves, not leaving that care entirely to the commendable but often inadequate efforts of private charities.

I would yield to no one in my appreciation of obstetric ideals and I trust you will see the desirability of correcting the erroneous imputation in your editorial comment.

Very truly yours,

A. K. PAINE, M.D.

A READER'S CORRECTION.

BOSTON, NOV. 24, 1915.

Mr. Editor: The BOSTON MEDICAL AND SURGICAL JOURNAL in its last issue published two articles discussing the problem of the midwife and the obstetrical situation in Boston. The paper by Dr. Paine was read before the Chirurgical Society of Boston when I was its president. I, therefore, feel at liberty and that it is only just to him to say that the conclusion which the editorial comment in the same number of the JOURNAL states as Dr. Paine's views is at a variance with the impression his paper made on the Society when he presented it and on me when I read it.

Dr. Paine begins his article by stating that his title is a misnomer and that the midwife represents but a part of the general situation. In his conclusions he definitely states that "our method of government is not adapted to the rigid requirements which the properly regulated midwife demands." His chief conclusion is that "the state should assume the management and control" of poor pregnant women through their pregnancies and confinements, not only because of humanitarian reasons but also because of the civic importance of the subject.

Before sending you this letter I called up Dr. Paine to be sure that I understood him aright and he said that he did not feel that the "midwife system of Europe" was one for us to adopt, but that it could not be lightly dismissed as *all* evil without careful consideration.

My purpose in writing you is to call your attention to the fact that the convictions of the authors towards the midwife problem do not differ so materially as the editorial comment would lead the casual reader to believe.

Cordially yours,

HILBERT F. DAY, M.D.

A QUESTION OF PRIORITY.

MOUNT SINAI HOSPITAL.

BOSTON, MASS., NOV. 19, 1915.

Mr. Editor: In reading the interesting article by Dr. J. L. Huntington on "Pregnancy Clinics" in the last number of the BOSTON MED. AND SURG. JOUR., I noticed an inaccuracy which I desire to call to your attention. Dr. Huntington states that "the Boston Lying-In Hospital was the first to establish a real Pregnancy Clinic in Boston in connection with its other work . . . It was started in 1911 and now there are at least three other similar clinics in Boston."

By reference to the published Annual Reports of the Mt. Sinai Hospital of Boston, you will find that the Pregnancy Clinic at this institution was started in 1908, under the name of Antepartum Clinic. The idea was suggested to the staff by Dr. A. K. Paine, and so far as we know it was given practical application for the first time at this hospital. In its early days only a small proportion of the applicants for treatment could be induced to submit to pre-natal examination and treatment, but now the majority are glad to avail themselves of the opportunity. Again reference to the Annual Reports will show that the treatments at this clinic were in 1908, 41; 1909, 44; 1910, 99; 1911, 156; 1912, 264; 1913, 346, and in 1914, 422. The deliveries in the past three years have averaged 350 per year.

From the start the clinic has been run along the lines which Dr. Huntington has developed in his article. In addition to a member of the obstetrical staff, who plans to see each patient at least once during pregnancy, we have a trained social worker who gives a good part of her time to investigating home conditions previous to delivery. Recently we have also inaugurated a system of "follow-up work" which covers special cases demanding particular attention after delivery.

Thanking you for the opportunity for making this correction, I am,

Yours sincerely,

S. A. Moulton, M.D.,

Superintendent.

SOCIETY NOTICES.

NEW ENGLAND PEDIATRIC SOCIETY.—The thirty-ninth meeting of the New England Pediatric Society will be held in the Boston Medical Library, Friday, Dec. 10, 1915, at 8.15 P.M.

I. Report of Council and nomination of officers.

II. Report of Treasurer.

III. The following papers will be read:

1. Simple Incision in the Treatment of Pyloric Stenosis, by James S. Stone, M.D., Boston.

2. Spasmodic: Report of Ten Cases.—Etiology and Treatment, by Fred P. Webster, M.D., Portland, Me.

3. Fermentative Diarrhea in Infants, by Lewis W. Hill, M.D., Boston.

IV. Election of officers.

Light refreshments will be served after the meeting.

F. M. BUCKINGHAM, M.D., *President*.
 RICHARD M. SMITH, M.D., *Secretary*.

HARVARD MEDICAL SOCIETY.—Historical club meeting in the Peter Bent Brigham Hospital Amphitheatre, Tuesday evening, December 7, 1915, at 8.15 o'clock.

PROGRAM.

1. "Surgery in London One Hundred Years Ago as Observed by an American Surgeon of the Old School." Dr. J. Collins Warren, Boston.

2. "Florence Nightingale and Modern Red Cross Organization." Dr. Maude E. Abbott, Montreal.

Medical students and physicians are cordially invited to attend.

ERNEST G. GREY, M.D., *Secretary*.

NORFOLK SOUTH DISTRICT MEDICAL SOCIETY.—Meeting for Medical Improvement, at United States Hotel, Boston, Thursday, December 2, 1915, at 11.30 A.M.

Reader, A. L. MacAusland, M.D., Boston, Mass., for Hjalmar Ahlstrom, M.D., Quincy, Mass. Subject: "Hip Joint Diseases and Injuries."

F. H. MERRIAM, M.D., *Secretary*,
 South Braintree, Mass.

SUFFOLK DISTRICT MEDICAL SOCIETY.—SURGICAL SECTION.—Meeting Wednesday, December 15, at 8 P.M., at the Boston Medical Library.

Address by Dr. William Rodman of Philadelphia, on "Surgery of Gastric Ulcer."

CHARLES L. SCUDDER, M.D., *President*,
 W. J. MINTER, M.D., *Secretary*.

NOTICES.

WAR LECTURES FOR THE BENEFIT OF THE SOCIAL SERVICE DEPARTMENT OF MASSACHUSETTS GENERAL HOSPITAL.

On Monday of next week, December 6, Dr. C. A. Porter and Dr. Robert B. Osgood will give at Sleeper Hall, Boston, at 4 P.M., the second of a series of war lectures for the benefit of the social service department of the Massachusetts General Hospital. This lecture will be on the work of the Harvard Unit in the hospitals of France. Tickets, at a cost of \$1.50 each are on sale at Herrick's at 1 Marlborough St., and at the Social Service Department of the Massachusetts General Hospital. Mail orders will be filled by this department. Checks should be made payable to Francis P. Sears, Treasurer, and sent to the hospital. These lectures are in charge of a committee of which Dr. Richard C. Cabot is chairman and among whose members are Dr. Daniel F. Jones, Dr. Roger I. Lee, Dr. Robert B. Osgood, Dr. James J. Putnam, Dr. Richard M. Smith and Dr. Frederick A. Washburn.

MASSACHUSETTS HOMEOPATHIC HOSPITAL.—Department of Clinical Research and Preventive Medicine, Evans' Memorial.—The Evans' Memorial for Clinical Research is desirous of coming into communication with as many physicians as possible who have used bacterial vaccines in the treatment of typhoid fever for the purpose of collecting statistics concerning the efficiency or non-efficiency of the method as a therapeutic measure. If any who have done this even with only one or a few cases will send their names and addresses, blank forms will be sent to them upon which uniform reports may be made. Due credit will be given to each in any reports that may be published. Kindly address all communications to Dr. W. H. Watters, 50 East Concord Street, Boston.

APPOINTMENTS.

Dr. George Adams Leland, Jr., of Boston, has been appointed associate in surgery at the Massachusetts General Hospital.

Dr. L. G. Rowntree of the medical department of Johns Hopkins University, has been appointed professor or medicine and chief of the department of medicine in the medical school of the University of Minnesota.

At the recent meeting of the Board of Overseers of Harvard College, Dr. Robert Williamson Lovett was elected to the John R. and Buckminster Brown Professorship of Orthopedic Surgery in the Harvard Medical School. The following administrative boards in graduate departments were also appointed:

Harvard Dental School, Dean Eugene Hanes Smith, Charles Albert Brackett, George Howard Monks, William Parker Cooke, William Henry Potter, Anos Irving Hadley, Samuel Tuttle Elliott, George Henry Wright, Leroy Mattheis Simpson Miner; Harvard Medical School, Dean Edward Hickling Bradford, Harold Clarence Ernst, George Gray Sears, David Linn Edsall, Reid Hunt, Robert Battey Greenough, John Lewis Bremer, Francis Winslow Palfrey, *ex-officio*; graduate school of medicine, Dean Horace David Arnold, Edward Hickling Bradford, Algernon Coolidge, Robert Williamson Lovett, Charles Locke Scudder, Frederick Taylor Lord, Walter Clarke Howe, *secretary*.

RECENT DEATHS.

DR. HENRY CHARLETON BASTIAN, who died recently at Chesham Bois, Buckinghamshire, England, was born at Truro, Cornwall, on April 26, 1827. He obtained his education at University College, London. Later he became instructor and professor of pathological anatomy at that institution until 1887. He then became professor of the principles and practice of medicine until 1895 after which he remained as professor emeritus. He was for many years consulting physician to the National Hospital for the Paralyzed and Epileptic in London and was a prolific writer on neurologic and psychiatric subjects.

DR. THOMAS C. TREADWELL, who died of nephritis on Nov. 18 at Stoneham, Mass., was born in New York City in 1863. He had practised in that city as a dentist for many years. He is survived by his widow.

DR. GEORGE HENRY WILKINS, who died recently at Framingham, Mass., was born at Amherst, N. H., on Dec. 28, 1855. After obtaining his preparatory education at the New Hampshire State College, he received the degree of M.D. from the New York Homeopathic Medical College. From 1883 to 1902 he practised his profession in Palmer, Mass., removing later to Newtonville, Mass., where he has served for the past ten years, as a member of the staff of the Newton Hospital. He was a member of the Massachusetts Homeopathic Medical Society, the Worcester Medical Society and the Springfield Medical Society and was a lecturer at the Boston University School of Medicine. He is survived by his widow.

DR. FREDERICK WILLIAM RUSSELL, a retired Fellow of The Massachusetts Medical Society, died at the home of his daughter in Dallas, Texas, Nov. 20, aged 70 years. He was a graduate of the New York University Medical College in 1870 and had maintained a private hospital, of fifteen beds, for mental cases in Winchendon, Mass., since 1875.

DR. BENJAMIN JOY JEFFRIES died at his home in Boston, Nov. 21, aged 82 years. He had been a noted ophthalmologist and had practised in Boston from 1859 up to the time of his retirement a few years ago. He was a counselor of The Massachusetts Medical Society from 1875 to 1908, and was the orator in 1888. For many years he had been librarian of the Suffolk District Medical Society, holding the office at his death.

NOTES OF A CONFERENCE ON THE MEDICAL AND SOCIAL ASPECTS OF SYPHILIS OF THE NERVOUS SYSTEM.

HELD AT THE PSYCHOPATHIC HOSPITAL,
MAY 27, 1915.

I.

REMARKS AT NEUROSYPHILIS CONFERENCE,
MAY 27, 1915.*

BY ABNER POST, M.D., BOSTON.

We have a very interesting matter under consideration at these exercises today. Syphilis of the nervous system has exercised the ingenuity and careful study of the authors of the papers read. To realize how important a matter syphi-

lis is in the community, one must remember that syphilis occupies the same important place in almost every public institution in the state. Syphilis in the Eye and Ear Infirmary is just as important as it is here. There is surgical syphilis and medical syphilis and internists are devoting just as much thought to syphilitic diseases of the internal organs as the people here are to cerebrospinal syphilis.

The financial aspect of the disease is extremely interesting. This is the only communicable disease where the community demands that the suffering individuals shall bear the expense of protecting the community. The individual with syphilis must pay for his own treatment or go without. We recognize him as an individual dangerous to the public health, and still the only place, practically speaking, where he can get his treatment in a manner to protect the community is in the State Hospital at Tewksbury. That is not of course absolutely true because there are charitable institutions and individuals who are interested in particular cases to whom they give individual help,—but as a rule the State makes the individual pay for his own fees and only in that way affords protection to the rest of the community. We take care of smallpox patients, we take care of patients with diphtheria, we spend large sums on tuberculosis patients and very large sums on a very small number of cases of leprosy, but the poor syphilitic must take care of himself. However, things are getting much better. The Massachusetts General Hospital has devoted a separate department to syphilis, with a large out-patient service and a small number of beds, and there is every reason to expect a permanent in-

* Being S. B. I. Contribution, whole No. 122 (1915.25). This and the following constitute a series of papers presented in full or in abstract at a Conference on Neurosyphilis: Medical and Social Progress, held at the Psychopathic Hospital, Thursday, May 27, 1915. Previous Psychopathic Hospital Conferences on matters of general psychopathological or special psychiatric interest have been held on Some Medical and Social Aspects of Mental Disease Due to Alcoholism, (before the Legislative Committee on Drunkenness) November 24, 1913, and on Modern Developments in Mental Nursing, February 16, 1914. These were published in the BOSTON MEDICAL AND SURGICAL JOURNAL of December 25, 1913; and September 24, 1914, respectively. Future conferences will deal with heredity, social service, mental hygiene, and other general topics with which the Psychopathic Hospital is vitally concerned, the whole series of conferences being designed to bring out the medical and social aspects of the psychopathic and psychiatric problem as it must be faced by the modern state. (Bibliographical Note.—The previous contribution was State Board of Insanity Contributions, whole No. 121 (1915.24) by E. E. Southard, entitled "Advantages of a Pathological Classification of Nerve Cells, with Remarks on Tissue De-complication as Shown in the Cerebral and Cerebellar Cortex," in Transactions of Association of American Physicians, 1915.)

crease in the ward accommodations in the future.

In the city of Memphis, within a year, they have so arranged matters that a doctor can send a man with syphilis to a hospital and he is received and treated as a matter of course, as if it were any other disease.

Salvarsan is an interesting drug and especially interesting at the present moment when it is becoming somewhat scarce. One must hope that there may be other possible combinations of equal therapeutic value, because it is inconvenient to be dependent on another country with such limited means of transportation as Germany has at present, and the financial aspect of the thing assumes some importance when we consider the real expense. It would seem that if the remedy were absolutely cut off, some of our chemists might be able to produce a remedy of somewhere near the same value which could be used without any special weight upon the financial condition of the State.

The social conditions of syphilis interest me extremely. The social worker has perhaps as delicate a task in attempting to improve the social conditions of the syphilitic family as any social worker has. It is a matter that requires tact, sympathy and patience, and it is a matter which presents most wonderful opportunities for mischief, and some of the earliest attempts at social work in behalf of syphilitics were unfortunate.

When the social worker goes into the family of a syphilitic, she must dismiss from her mind any presupposed guilt.

Syphilis is perhaps the only crime in which it is taken for granted that the individual is guilty. Of any other crime it is assumed that he is innocent until his guilt is proven, but socially, morally and physically, we have for generations taken it for granted that the person with syphilis is guilty of some lapse from morality, and one cannot expect that patients who are approached on that basis will always be responsive. It is not strange that stories differ when patients are approached by different individuals, each one convinced that the patient owes his misfortune to his own evil deeds. It is not surprising that patients should refuse to tell the truth when they see a lady come in with a notebook and pencil and they know their own confessions are going to be put down in black and white. I think we owe it to our patients that the recorded history shall not always be absolutely full. There are some things which ought not to be put down in black and white, which do not necessarily contribute to the value of the history; and one must remember that the number of innocents is really very great. Of the innocent infections in which the seat of infection, such as those on the lips or tonsils or fingers is known, there are somewhere near 8-10%. One in every ten or twelve is too large a proportion to be ignored. If you think of 1000 syphilitics—and it takes a very short time to count

up 1000 in a hospital of this size,—there are between 80 and 100 innocent infections. If in addition you will consider the individuals who are innocently infected in marriage, the innocent husbands and the innocent wives who are thus infected, and the hereditary cases,—you have a very large number of innocent syphilitics. I am not sure that 50%, taking all the different data, is at all too large a percentage for the number of innocent syphilitics. And even if the syphilitic is not innocent, the suffering which syphilitic parents undergo in seeing their syphilitic children grow up about them is something terrible. There are few doctors who have dealt with syphilitics who have not in mind case after case where father or mother has come to talk the matter over, to make sure that the doctor really understands the case. If any class of individuals need sympathy, it is the syphilitic parents. I cannot help thinking of the advice given by his father to a friend of mine: "John, if your friend is in trouble, stick to him; if he is in trouble and it is his own fault, stick to him, for that is when he needs you."

There is one sentence in a textbook on social service in an article on syphilis which states that no matter what the condition of the syphilitic may be, it will always refer back to a venereal source. One might add to that clause that if you will investigate further, you will find an innocent case connected with it also.

I am very anxious not to misstate or exaggerate. Without any regard to numbers, some such statement as this would express my meaning:

The innocents are too many to be ignored:

The immoral are not all lost souls; some of them are to be numbered with those repentant sinners who cause more joy in heaven than those who never went astray:

The innocent and guilty are so mingled that only the All-Seeing and All-Knowing can absolutely separate them:

Many are already suffering the torture of an earthly hell, and it is the function of Social Service to seek and save rather than to judge in a cause of which our knowledge is at best very imperfect.

The percentage of syphilitics in the Psychopathic Hospital, according to Dr. Southard, cannot be very different from the number found in the community. There have been a good many attempts to get some idea of the number of individuals who either have or have had syphilis, for syphilis is so chronic a disease that in matters of census-taking "once a syphilitic is considered always a syphilitic." In Paris some investigations by Fournier resulted in a statement of something like 17% in the general population. Dr. Hyde of Chicago made some calculations in which he thought the population of Chicago was syphilitic to the extent of 15% and it is somewhere in that vicinity—between 10% and 20% in all probability, as far as one can get any idea from figures. This is certainly a suf-

ficiently large number; but there is no sense whatever, as Dr. Southard has already said, in talking about 50% of the population being syphilitic. One must keep in mind also in thinking of syphilis, that not all syphilites are equally dangerous. The danger is confined practically to the individual whose syphilis is comparatively fresh and who has external moist lesions, so that the mere presence of a syphilitic is not by any means a source of danger. Syphilis is one of the least dangerous of communicable diseases.

It is natural, right and proper that in such studies as have been made here that the scientific diagnosis should be especially emphasized. If you wish really to draw conclusions which shall be convincing to others, you need the scientific data, but the clinical study of the disease needs to be stimulated. When one hears so many stories of individuals with scientific proof of syphilis in the entire absence of clinical lesions, it seems worth while to accept the statement with a little hesitation, because the clinical signs are not studied as carefully as they ought to be. Notwithstanding that they have been studied for years, it is difficult to feel absolutely sure about the syphilitic character of some of the children of syphilites, and even those with absolutely convincing clinical signs do not all show positive Wassermann.

We may all feel gratified at the interest shown in the meeting today, and as a community we ought to be grateful for the interest added to the study of syphilis by the Psychopathic Hospital.

II.

EXAMINATION AND PROPHYLAXIS FOR SYPHILITIC PATIENTS AND THEIR FAMILIES: METHODS OF INVESTIGATION AT THE PSYCHOPATHIC HOSPITAL, BOSTON, MASSACHUSETTS, 1915.*

BY HELEN M. WRIGHT, BOSTON,
Social Worker.

THE worship of Esculapius and Hygieia, which meant so much to the public life of the Greeks, is reflected today in our modern enthusiasm for health of mind and body. Our public has been aroused and has demanded careful inquiry into methods of maintaining good health and of preventing disease. It is manifesting itself not only through such organizations as the National Committee on Mental Hygiene, American Social Hygiene Association, The National Association for the Study and Prevention of Tuberculosis, and the American Medical Association, but also through public health officers, private physicians, hospitals, and dispensaries, public and district nursing associations, school boards, women's clubs, consumers' leagues, boys' and girls'

scout organizations, popular magazines and other publications, and even through smaller agencies, such as mothers' meetings and settlement classes. Through such forces research is being encouraged and its results brought to the attention of the eager populace.

The history of the development of public health inquiries, from the determining of causes to the study of methods of prevention, points out four directions along which investigations have been projected, namely:

(1) examination, (2) history, (3) treatment, and (4) education, each of which involves first of all the study of causes and relations. The study of the causes of the various stages of syphilis belongs to the laboratory and to the clinic. Relative social histories may sometime make a contribution by showing the patient's reactions to his environment during different stages of the disease—but as yet the social aspect of work with these patients has been confined to the four branches of investigation just mentioned. Each is closely related in turn to the patient, his family, and the community.

In the Psychopathic Department of the Boston State Hospital, where the problem of neurosyphilis is a large one, the physicians and laboratory workers are on the alert for new signs, new reactions, and new conditions found in syphilitic patients. As a basis for thorough consideration of a patient, an effort is made to have every person, admitted to the House or Out-Patient Department, given a clinical *examination* and a Wassermann test for the blood. In each case, where possible, a social history¹ is obtained. Those patients showing evidence of syphilis or organic nervous disease, are given a lumbar puncture (the spinal fluid is examined). Through this routine use of the Wassermann test, combined with the other means of identification just noted, and with the extensive use of the lumbar puncture, many cases of syphilis and neurosyphilis have been revealed, which otherwise could not have been recognized. In this way, therefore, *examination* is here used as a method of investigation.

The second method, *that of obtaining history*, through clinical facts and social records, has been the earliest one used by the medical profession and the one most generally employed. The nature of the inquiry,—the particular data sought for,—must perforce, change greatly from year to year.

Because of the lack of adequate appropriations from the State, the high price of salvarsan, which places it beyond the purchasing power of most patients, and the great difficulty in securing salvarsan since the beginning of the war, there have been but a very small number of patients treated. *This salvarsan treatment has been given chiefly to certain neurosyphilitic patients, who have been chosen as an appropriate basis for study.* Here, then, we find our *third method of investigation* applied in the hospital.

The fourth, above designated as *education*, is

* Being S. B. I. Contribution whole number 123 (1915.26). See footnote to Remarks at Neurosyphilis Conference, May 27, 1915, by Abner Post, this number, BOSTON MED. AND SURG. JOUR., page 867.

developed through the confidential relation between the physician in charge and the patient. He it is who draws for the patient the laws of hygiene which he needs for himself and which will guide him in his relations to his associates. The physician also interprets to the patient's family the significance of the disease in each specific case. Through the reactions of both of these groups, the patients as individuals, and their families as related individuals, research workers should learn something in regard to methods to be employed or not to be employed in the propaganda against the spread of syphilis, and indirectly in the propaganda for sex education.

The ideal of education is also embodied in the research work of the hospital. Any worker who may have contributed to some part of the inquiry already made is urged to collect and classify the data secured, and to draw conclusions therefrom.

The social aspects of each of these four lines of investigation, as used in this hospital, have developed gradually. Social Service was called upon by the medical staff to perform many supplementary duties which at first seemed unrelated to each other. Very soon, however, they assumed the form of a great social need and pointed out a very definite program whereby Social Service championed not only the cause of the individual patient, but also the cause of research or inquiry.

The social aspect of examination, for example, first appeared when some of the following types of cases were referred to the Social Service. The attending physician asked to see the wife and daughter of Mr. X—, a house patient with cerebrospinal syphilis. The wife had been advised to come to the Out-Patient Department, but had refused. It required several letters and visits from the Social Service to locate the family and bring them in for examination. The Wassermann reports were positive for the wife and doubtful for the daughter.

In another case, a child, James, sent to the Out-Patient Department with question of feeble-mindedness was found to have "doubtful Wassermann." After much effort on the part of co-operating social agencies and the Social Service, the three sisters and mother were examined, and the mother was induced to allow James to enter the House for a lumbar puncture. It was found that the patient had cerebrospinal syphilis, one sister had congenital syphilis and the mother had a positive Wassermann reaction of her serum.

Not only was the Social Service called upon to bring in other members of the patient's family,² but often the patient himself had to be visited and urged to return for a second Wassermann, when the first was doubtful. In cases where clinical evidence indicated neurosyphilis, it was frequently necessary for the social worker to convince him or his family, of the importance

of his entering the house for observation and lumbar puncture.

There were many instances also of patients with a syphilitic history, whose children had negative blood tests, but showed a poor physical condition, which suggested the need for observation. These children, when examined at this hospital, were referred to the follow-up system, to be asked to return for further examination at the end of a year or six months, according to the physician's advice.

So many of these duties relating to examination were asked of the Social Service that there became evident the need for a system by which every syphilitic patient known to the hospital should receive the attention of a social worker. In October of 1914, a card catalogue³ of syphilitic patients was introduced, and an effort made to bring to the hospital for examination the patient's spouse, if married, and every member of the patient's family under 18 years of age. A few exceptions were made in certain cases where the patient had a primary infection, and the family had not been exposed. When the patient was a minor, his parents were sent for and his brothers and sisters under 18 years of age.

The work done by this routine system was called "Examination and Prophylaxis for Syphilitic Patients and Their Families."⁴ These patients were not registered as Social Service cases, except in particular instances when the worker, on learning the condition of the patient's home, found it necessary to do more than have the family examined, or give them slight service or advice.

In an analysis made of 2050 admissions to the house from April 1, 1914, to April 1, 1915, there were 329 syphilitic patients. One hundred and eleven of these were already known to social agencies, 41 were aided in various ways by the Social Service of this hospital and 69 others were given oversight by the workers interested in the prophylaxis for the family. Through the efforts of this particular branch of the social work, 107 persons were brought into the Out-Patient Department for physical examinations and blood tests. They came from families representing in total 839 living individuals, 251 of whom were under 18 years of age. The 107 persons examined were chiefly those under 18 years of age. As the need for this particular kind of work grew, it was found that it required the full time of a worker, and through the interest of a philanthropic woman, it was possible on May 1, 1915, to engage a special worker for six months.

Although in this routine way, we are reaching the need for the examination of our patients and their families, that of others in the community at large cannot be met under present conditions, both because of the lack of free clinics and because of the still existing prejudice among the people against reporting at a syphilitic clinic

when in their minds "there is nothing the matter" with them.

The most natural way to solve this problem would seem to be through the public school physician. If society should think it advisable through the Board of Health or the Public School Board to require the registration of certain physical stigmata, and make a Wassermann test on every child examined, we should then be in a position to know the seriousness and the magnitude of the problem of congenital syphilis.

Returning to the second method of investigation, *that of securing histories*, we have found that the importance of the social history has been especially emphasized by this hospital. For the first patient coming to the Out-Patient Department, from any family, a long full history has either been taken by the historian or obtained from a social agency acquainted with the case. But for the families of syphilitic patients it seemed wise to have a special form which would record the particular data characterizing each individual member of the family.

For the sake of uniformity a blank questionnaire was adopted, which called for the identifying information and offered suggestions for the individual's story, these suggestions being grouped under the headings of prenatal and developmental history, illnesses, education, work, recreation and character. An effort has been made to secure particularly his traits of character, special gifts or talents and special defects or delinquencies. These special histories have been obtained for the syphilitic patient's spouse and children, and in cases of minor patients, have included the brothers and sisters and parents. It is safe to say that with the exception of those of the parents of minors, this group of histories represents the social records of persons innocently infected and of persons related by birth to infected patients. The information contained should be of value at some later date.

Patients suffering from the effects of recklessly acquired syphilis, are found chiefly in the *House*, and for them the historian, because of lack of time, has been able to secure but a very small number of outside social histories. This is to be regretted, as it seems particularly important to have a careful and impartial life story of these patients, if one is to obtain any clue as to the particular innate characteristics or social conditions, which contributed to the individual's exposure to the disease.

In the analysis of the 2050 House cases, previously referred to, the small number of records which did have outside social histories showed many discrepancies in the patient's story, especially where he gave a negative history. The social data, therefore, taken from the patient's story as given to his physician only, have probably fallen short of the truth, but a few of the social facts, which this analysis showed in the lives of these 329 syphilitics should be of interest nevertheless. (See Chart I.)

Let us call their most common social difficulties hazards, and compare the numbers of those hazards acknowledged by the syphilitic patients with those of some 1200 House patients chosen at random. There were very few of the syphilitic patients who did not have two or more of those difficulties, varying in degree of seriousness. There were 19.4% of them with court records as compared with 10.2% of the patients chosen at random. There were 49.5% of them with an acknowledged history of alcoholism, against 35.9% among the other patients; 15% of the syphilitic patients had a known sex history, which had involved social complications; whereas but 7.9% of the second group were so distinguished. Another hazard which was fairly conspicuous was that of the men and women living apart from their families and alone, designated on the chart under the name of Homelessness. Of these there were 20.3% among the syphilitic patients as compared with 5.8% in the study made of the 1200 House patients chosen at random. If the histories represent these characteristics even in part, it would seem that further inquiry along these lines would be useful to organizations concerned with the alleviation of the social evils.

The social investigation concomitant with treatment has been varied and difficult. The most serious problem has been how to get money to pay for the salvarsan when such treatment has been recommended. But very few patients have acknowledged the ability to pay for themselves. In a few other cases, the Social Service

has been able to secure the money from the patients' relatives or from social agencies, already interested. There have been, however, other patients not known to any social agency and not having relatives to help them, who could not have had treatment had not some benevolent individual come to his assistance. This aid, however, has been very difficult to get because the common answer to the request for money has been that provision for the treatment of such patients was distinctly a state problem, and should be financed by a state appropriation. The relief agencies, both public and private, have refused to aid these patients, and private individuals have thought there were more encouraging cases, making demands upon their purses. Added to the above-named types of patients, for whom social service has had to raise money, have been certain neurosyphilitics who seemed in every way socially hopeless. This type has usually been a man living apart from his family, and having a bad record from early life, intermittent employment, if any, and an added loadstone of alcoholism, but who had the disease in a stage, which, to the physician gave promise of certain definite reactions to treatment. For scientific and research purposes it seemed advisable to provide the necessary money.

From the 329 syphilitic patients of last year, 164 were transferred to hospitals for the insane, and 9 died here. The matter of treatment was thereby simplified, but was still a problem. In the light of the difficulties under which treatment has been secured for the patients, it is not surprising that among 51 house patients advised to have salvarsan only 26 received it. Infected persons found in the patient's family, unless they have shown nervous symptoms, have been referred to other hospitals for treatment.

The treatment of these syphilitic patients, therefore, presents a great public problem.

Investigation made by the Social Service along educational lines thus far has been limited. It has endeavored to find the best method of giving instruction to syphilitic patients and their families. So far instruction has been confined almost entirely to families in which the physician has made a first explanation. In this way, but a very small number of persons are reached. Perhaps as the idea of the health center grows, the social service of such an institution as the Psychopathic Hospital will become a community health center so organized that the evening clinic, men's clubs, mothers' meetings, and health conferences and exhibits will be educational centers, where syphilis and allied diseases can be discussed as openly as one now speaks of tuberculosis.

As an educational method of investigation, the keeping of records of these patients, and the collection of data has been considered. As one result, a card has been especially designed for the Prophylaxis System, which shows at a glance

the relation of every member of the patient's family to each other in respect to their age, laboratory tests and social treatment, and providing a ready index to the case file numbers. There were also adopted uniform history blanks for the members of the patients' families coming to the Out-Patient Department, and these have helped to secure a uniform collection of social data for this particular group of patients. Should the public school authorities introduce the special physical examination and Wassermann tests as part of their régime, a portion of these hospital data would be of great value for comparison with the records of the normal children in the schools. But as yet our work is so young that studies made from our data can be used only as sign posts.

Just one more reference to the study of the 329 syphilitic house patients of last year, as an illustration of the educational method of investigation. It gives the classification of these patients according to their diagnoses. (See Chart II.) Those found to have general paresis, cerebrospinal syphilis, tabes and allied diseases, formed 40.4% of the total and 79% of them were men. Those diagnosed as manic-depressive psychosis, senile dementia, drug psychoses, or other psychoses not noted below, formed 16.1% of the whole, of which 54% were women. The alcoholic and the dementia praecox groups were next in proportion, each with a percentage of 11. Among the alcoholics, the male predominated with 54%, while in the dementia praecox group the female predominated with a percentage of 64. There were 9.4% feeble-minded and defective delinquent, 58% being female. The not-insane group was 8.2%—51.8% of which were men. The congenital syphilitic group of 3.7% had 75% boys.

If an analysis of the social histories of these syphilitic patients were made and the data classified and arranged in groups according to diagnoses as above, and if these data were compared with corresponding groups from the histories of non-syphilitics, some enlightening similarities and dissimilarities in character, traits, and conduct ought to be found.

CHART II.—HOUSE PATIENTS.

2050 Admissions—329 Syphilitic Patients.

Diagnosis	Syphilitics	Predominating Sex
General paresis	40.4	M. 79
Cerebrospinal syphilis		
Tabes		
Manic depressive	16.1	F. 60.3
Senile dementia

Not insane	8.2	M. 51.8
Congenital syphilis	3.7	Boy 75
Juvenile paresis		

By means of the four general methods of investigation, and their more detailed subdivisions, as used at the Psychopathic Hospital, an attempt is being made to meet the problem of syphilis as it is related to nervous and mental patients, their families and the community. But without broader methods of investigation the efficiency of this work is limited. The need for certain extensive methods, whereby the general state and city institutions will cooperate with the more specialized institutions, has already been referred to. There are other methods which will contribute to a greater knowledge of the disease and its relation to society.

The reporting of venereal disease to State or Municipal Boards of Health, either by statute, or by rule of the Board, is decidedly a step in advance. There are now at least eleven states in the Union which have adopted such a system. Recognizing the fact that public sentiment has not yet asked for it and that the requirements by rulings without penalty may be generally ignored, Vermont has recently passed a law requiring the reporting of venereal disease, by name, sex, age and address, by any physician who treats or prescribes for a case, and providing a penalty not to exceed \$200 fine for failure to report. Through the repeated efforts of the various states and through their failures there will undoubtedly evolve a general system by which venereal disease will be detected, registered and controlled as tuberculosis now is.

Public boards will also provide appropriations whereby therapy for venereal disease will be put within the reach of those who can pay little or nothing for it. Smallpox and tuberculosis have been so dealt with.

All who are promoting social welfare or health measures recognize the importance of securing intelligent cooperation from the people rather than relying entirely upon the enforcement of legislative and other measures.

For this reason public exhibits, clinics, meetings and conferences, which will not only be open to the people, but will seek them in their own localities, will all help in the general appreciation of the problem of syphilis and allied diseases, so vitally related to the family life of our country.

SUMMARY OF METHODS OF INVESTIGATION USED AT THE PSYCHOPATHIC HOSPITAL.

1. A free clinic where a physical examination and blood tests are given.
2. A routine follow-up system for all syphilitic patients, including examination and prophylaxis for the members of their families.
3. A uniform method of recording families of syphilitic patients by card catalogue.
4. A special history blank for the families of syphilitics whereby uniform data can be collected.
5. A social worker who investigates the cases of syphilitic patients and arranges payment for salvarsan treatment, when necessary.

6. Patients with active syphilitic infections have been instructed to safeguard their families.

7. Instruction has been given to patients and their families regarding preventive and therapeutic measures and an effort made to show them the importance of keeping children of syphilitic parents under medical observation.

8. Study of problems relating to syphilitic patients has been encouraged.

SOME RECOMMENDATIONS FOR BROADER METHODS OF INVESTIGATION.

1. A system by which every syphilitic House patient at the Psychopathic Hospital shall have a social history obtained from outside sources.

2. The use of the Wassermann test in suitable cases and a standardized method of recording physical stigmata for all children in the public schools.

3. A public (Board of Health) registration of all persons having a history of syphilis, either by name or by number.

4. A state appropriation provided whereby salvarsan treatment may be used for therapeutic and research purposes.

5. Methods of providing public presentations of scientific data in form which the lay public can interpret for itself.

6. A Health Center, including evening clinics, men and women's clubs, conferences, and exhibits where information under medical supervision, may be given regarding syphilis, and allied diseases, as well as other mental and social hygiene questions.

BLADDER TUMORS IN THE YOUNG.*

By R. F. O'NEIL, M.D., BOSTON.

Genito-Urinary Surgeon to Out-Patients, Massachusetts General Hospital.

THE occurrence of bladder tumors in relation to tumors of other organs has been variously estimated as from .39% to .76%. It will readily be seen when studying the series of reported cases that neoplasms occurring in the young make up but a small percentage of the cases.

In the carefully prepared series of Albarran¹ of 252 cases there were but 6 occurring from one to ten years of age, 3 from ten to twenty and 16 from twenty to thirty. In a series of 114 cases

* Read before the American Urological Association at the annual meeting in Baltimore, April, 1915, as a part of the Symposium on Bladder Tumors.

[For the purpose of this symposium the term "young" is interpreted to mean growths occurring in patients under 30 years of age.]

of bladder tumor including cancer from the Mayo Clinic reported by Judd,² there was but one case under ten, which case should not be considered as a primary bladder tumor, being an angioma involving the rectum and bladder. There were 3 cases between ten and twenty and 5 between 20 and 30 years. In 62 cases of tumor of the bladder from the records of the Massachusetts General Hospital from 1879 to February, 1915, there is only one case occurring in a patient below twenty. This was a case of sarcoma in a boy of sixteen. There were 4 cases between twenty and thirty. At the same institution in 129 cases of cancer involving the bladder, there was one case of adeno-carcinoma in a girl of eighteen, one case of epithelioma in a woman of twenty-seven and an inoperable carcinoma of the bladder in a man of thirty, the last case being open to doubt as diagnosis was by cystoscopy. Judd reports a case of carcinoma in a patient of seventeen.

It would seem therefore for the purposes of this paper that the selection of thirty as an arbitrary limit for growths in the young is not unreasonable as by far the greater number of cases occur after that time. This limit falls naturally into a further subdivision by reason of the pathology of bladder tumors, one group including the decades from 1 to 10 and 10 to 20 years during which the growths met with are practically always of the connective tissue and muscular type as sarcoma, fibro-sarcoma, myoma, etc; the second group consisting of the decade from 20 to 30 years when all types of growth are met with.

The first group, including as it does infants and children and having a different symptomatology and pathology, is the one with which we are principally concerned and really represents bladder tumors in the young.

Group two may be regarded as being made up of sporadic and unusual cases resembling in symptoms and course the lesions met with later in life and are unusual only because they are comparatively few in number.

Bladder growths in infants and children are distinctly rare and little is to be found about them in the text books on pediatrics and the surgery of children. The literature previous to 1900 was more or less scattered and consisted of case reports and a few articles, theses and series of cases. In that year appeared in the *Archives de Médecine des Enfants* an original article by Concetti,³ of Rome called, "Les tumeurs malignes de la vessie chez les enfants." He reports a case in a female child of 11 months and gives a general description of the subject based on a study of 41 other cases collected from literature. A later contribution is made in 1905 by Steffen⁴ in a book entitled "Die Malignen Geschwülste im Kindesalter." He also gives a general description of the subject based on abstracts of 32 cases collected from literature. The conclusions reached by these two are very similar

and their tables contain a number of the same cases. Since this time has appeared an Inaugural Dissertation by Hüslér,⁵ Basle, 1905; some references in general papers on bladder tumors and some case reports. From the study of these articles certain points stand out in regard to these growths in children. In the first place the great majority are met with during the first five years of life. In Concetti's series there were 2 during the first year, 10 from the first to the second, 7 from the second to the third year, 5 from the third to the fourth and 5 from the fourth to the fifth. After that, the number falls to not more than one or two for each year up to seventeen.

In Steffen's series, 20 cases occurred from the first to the fourth year and 8 from the fourth to the twelfth. In an analysis by Munwes¹⁶ of 98 cases of sarcoma of the bladder there were 19 cases below the age of twenty and of these 10 were from one to five years and 5 from five to ten years old. According to the former the great preponderance of cases appearing so early in life is strongly in favor of their embryonic origin. The pathology of Concetti's cases is of interest as bearing out the fact that epithelial tumors are not met with at this age. In this connection Albarran reports 198 epithelial tumors without finding one under twenty years of age.

Concetti's cases were divided as follows:

Sarcoma	13
Lympho-sarcoma	2
Fibro-sarcoma	7
Myxoma	8
Myxo-sarcoma	2
Fibro-myoma	6
Dermoid cyst	1
Undetermined	3

All of these tumors are of connective tissues type and the large majority are malignant. In only 6, the fibromyoma, is there a question of their being benign.

Targett⁶ in an article on sarcoma of the bladder in children states that all these polypoid growths which are attached to the mucous coat of the bladder and variously described as mucous polyp, fibro-sarcoma, fibro-myxoma, myxo-sarcoma and the like should be described as sarcoma. The vast majority of primary growths of the bladder in children are polypoid in type, that is, they are rounded elevations of the mucous membrane with a more or less constricted base or pedicle and often arranged in clusters. Their macroscopical appearance may differ, also microscopically the proportions of fibrous, cellular or other elements may vary but they are pathologically better considered under one group, as clinically they certainly have one point in common, being almost uniformly fatal.

I say almost because of the recent report of a case by Robitschek⁷ of a boy 4½ years of age in whom he had excised a tumor of the bladder two years before; there had been recurrence during that time. The pathological diagnosis was

"telangiectic fibrous polypus." Koll⁸ also reports a simple polyp occurring in a child of 13 months cured by operation. A case reported by Shattuck⁹ is of interest in this connection being the bladder of a 2 year old child showing multiple polypi which were histologically composed of striated muscle. The case was thought to be congenital. However, these cases are potentially if not pathologically malignant.

These tumors always start from the mucous or submucous coats of the bladder, generally from the trigone between the ureteric orifice or near to the so-called neck of the bladder or vesical outlet. They may be single or multiple, generally the latter, with a long or short pedicle, or they may be sessile in character. They vary greatly in size and may have a lobulated appearance like a bunch of grapes and at times may fill the entire bladder.

They tend to recur very rapidly after removal¹⁰ but do not form metastases; they may directly invade the surrounding structures as the vulva, vagina, uterus, prostate or abdominal wall. They have a tendency to infiltrate the mucous and submucous coats not only of the bladder but of the ureter as well, causing considerable thickening of the bladder wall. As they almost always interfere with micturition by blocking the urethra, muscular hypertrophy of the bladder is present, also as the ureteric orifices are often involved the usual chain of back pressure symptoms with dilatation of the ureter and kidney pelves are met with, subsequent infection often occurring with fatal results. Death may also be due to exhaustion, cachexia or anaemia. The first thing generally noticed is some disturbance of micturition, pain, tenesmus, sudden retention or incontinence. There is often pain in the lower abdomen and what is very constantly described in the case reports as severe straining on micturition. The examination of the urine is at first negative, later signs of cystitis are present and sometimes bits of tumor have been found. As these growths do not tend to ulcerate at first, the characteristic hematuria of tumor is often absent, although when present, particularly following instrumentation, is very suggestive.

The symptoms are often suggestive of calculus, in male children pain being referred to the glans penis and many instances of elongation of the prepuce are recorded due to the attempts to get relief from traction upon the organ.

Irregularities in the contour of the bladder wall have in some instance been detected with a searcher and the diagnosis made in this way; also, incrustations of the growth have been mistaken for stone, as in adults.

In female children the tumor or parts of it may be forced out of the urethra by the straining on micturition combined with the pressure of an over distended bladder and appear as a mass in the vulva; a number of such cases are reported. Here the diagnosis should not be difficult.

Care, of course, must be taken to differentiate it from growths of the vagina or uterus which occasionally occur. Examination under an anesthetic will be necessary and will settle the question.

Occasionally the diagnosis of bladder tumor will be made when the symptoms are due to some extra vesical condition making pressure on traction on the bladder and causing urinary symptoms which can only be discovered at operation. I have found several such cases in the records of the Children's Hospital in Boston. One a tumor of the space of Retzius and perineum, causing marked urinary symptoms; in another a tumor apparently starting from the prostate and involving the side of the pelvis, causing retention. Still another being an infection of the prevesical space.

Diagnosis in the earlier stages on the whole is difficult. Some of the older children it is of course possible to cystoscope under an anesthetic. But in the young male children this can not be done. A child's bladder is readily palpable and a mass above the pubis with pain and urinary symptoms in the absence of congenital structure should excite suspicion.

At this point, I think it will be of interest to give the clinical histories of three of the reported cases which are selected as being typical and illustrate well certain points.

CASE 1. A case reported by T. A. Southam¹¹ in the *British Medical Journal*, July, 1894, of a boy of nine, good health till one year previously when he had an attack of hematuria lasting 24 hours and associated with pain and frequency. This disappeared and he was well for several months when he began to have incontinence at night and increased frequency during the day. Micturition was accompanied by severe straining, pain at the end of the penis and at times a little terminal hematuria. Prepuce very long from traction. Rectal examination slight tenderness at bladder base. A rough area on left side of bladder neck was felt with a searcher but no calculus. A perineal operation was performed as a new growth was suspected. A sessile growth the size of a quarter was removed with a curette from the left side of the bladder. This gave relief for about 5 months when there was a return of the symptoms. A second operation was performed but the patient failed and died 4 months later.

Pathological examination showed a round and spindle cell sarcoma.

CASE 2. Same author and reference. A boy of six years thought to have retention of urine from a calculus impacted in urethra. There was incontinence, bladder distended to the umbilicus and some obstruction to catheterization which felt "rough."

For nine months previously there had been increased frequency with "straining" and later pain and incontinence but no bleeding. Under chloroform the bladder was found greatly distended, a catheter was passed with difficulty but only two ounces of urine obtained which had no effect on the size of the tumor. Irrigation brought away fragments of the growth the size of a small pea. On

opening the bladder through a suprapubic incision masses of grey translucent polypoid growth varying in size from a pea to a pigeon's egg presented having very much the appearance of a bunch of grapes. Some of these were removed but the growth was so extensive the attempt was abandoned. The patient died on the second day after operation.

Post mortem. Growth found to be mixed sarcoma springing from the mucosa and submucosa but limited to the bladder, almost the entire mucous membrane was involved. A polyp extends into the urethra, blocking it. The kidney pelvis were dilated.

The first of these cases illustrates how the symptoms may resemble those of calculus. And the second, how a tumor may simulate a full bladder with retention and overflow, particularly where there is obstruction to catheterization still more resembling stone, which is a more common cause of retention in male children than is tumor.

CASE 3. Reported by Sims¹² in the *Medical Record*, April 1896 illustrates another type. The patient was a colored girl of 3 years of age. For three days she had passed no urine except a little that dribbled. For the past 18 months she had much difficulty in emptying bladder and bowels. There was marked straining. Three months ago swelling appeared in lower abdomen. Examination showed a prolapsed rectum and a mass the size of the finger presenting at the vaginal outlet. The bladder was distended. A catheter was passed with difficulty and the abdominal tumor disappeared on emptying the bladder. As the child was in extremely poor condition, no operation was done at that time. Ten days later the mass slipped back into the bladder of itself and later some of it sloughed off and was passed, after which she was better for a time. Soon, however, obstruction returned and the tumor prolapsed again. Immediate operation was done by dilating the urethra, pulling down the mass and removing it with scissors from the anterior wall where it was attached. The mass weighed 3 ounces and is described as a myxo-fibroma. There is no further report.

Another curious case is reported by Savony,¹³ an infant of 13 months, symptoms of stone, evident pain on micturition, an abscess developed in the abdominal wall, extending from pubes to umbilicus which on being opened discharged urine. Autopsy disclosed a large soft pedunculated tumor occluding the urethra. The urachus had become dilated by back pressure, the abscess connecting through it with the bladder.

The prognosis in cases of tumor in children is extremely bad. In the series of Concetti, the sarcoma, 32 in number, all died. Of the so-called benign cases, 7 in number, 3 died without operation, one of anaemia, one of pyelonephritis and one of uremia, so these tumors were clinically malignant if not pathologically so. Four were said to be cured by operation. One case of Bryant¹⁴ was described as a small papilloma which was removed by the eye of a catheter from a girl 3 years old, said to be well 11 years later. The second case of Gussenbauer,¹⁵ a male patient of

12, no further account except the operative recovery is given; a third, the case of Barth in Albarra's¹ table, a male of 17 showed a growth in the bladder 2 months after operation. These cases are very unconvincing. The fourth reported by Albaran, a male patient of 16, said to be well 2 years after the removal of a long pedicled polyp described as a fibro-myoma. The case from the Massachusetts General Hospital records may also be cited, a boy of 16 from whom a fibro-myo-sarcoma was removed. Well one year after operation, no further report.

Of Concetti's cases, 19 were operated upon, of these 9 died of rapid recurrence, 3 of peritonitis, 2 of shock, the others of infection of the urinary tract, cachexia, etc.

The operative measures were suprapubic cystotomy, perineal cystotomy and in female children dilating the urethra, pulling down the tumor and either ligating or euretting the growth away. The latter procedure being followed by rapid recurrence.

To sum up, vesical tumors in children are a very great rarity. The great majority appear before the fifth year. They are of the connective tissue type and are clinically and pathologically malignant except in rare instances. Difficulties of micturition are generally the earliest symptom; in the absence of stricture they should excite suspicion. Straining is common. Early diagnosis and operation offer the only hope of recovery. With the more exact means of diagnosis now at our command it is to be hoped that this can be accomplished.

In regard to the second group of cases occurring in the decade from 20 to 30 years of age: During this period both epithelial and connective tissue types are met, in 16 cases from Albaran's table between these ages, 8 were epithelial and 8 were connective tissue type. The sex distribution is interesting here, there being 11 male and 5 female. Of the 8 epithelial growths, 7 were male and 1 female. Of the connective tissue type, there were 4 each. These coincide with the cases occurring late in life in which the epithelial types predominate and males are affected about 3 to 1. In the connective tissue growth in children the sexes are affected about evenly.

In the series of 114 cases from the Mayo Clinic, only 5 occurred during this decade. In a paper from the same clinic entitled "Results in the Treatment of Tumors of the Urinary Bladder,"¹⁷ I found the report of 4 cases aged 20, 22, 27, and 29 which were operated upon and all have since died.

Of the 62 cases of tumor from the Massachusetts General Hospital records, there were but 4 during this period. All of these made operative recoveries, in 3 the further history is unknown. The fourth case, a woman of 29, from whom a tumor size of a walnut was removed through the urethra, died 13 years later of tuberculosis of the lungs. Unfortunately there was no pathological report on the specimen, but the clinical history suggests papilloma.

In a series of 24 cases of tumor of the bladder, Pilcher¹⁸ reports one case of a girl 20 with recurring malignant disease of the bladder, apparently successfully treated with the D'Arsonval current. Bremmnerman¹⁹ reports a case of 24 years of age in which the papilloma was successfully treated by fulguration.

There are occasional other cases reported, but they are not very common and the results of treatment in the majority have been highly unsatisfactory.

Before closing, I wish to say a word in regard to the occurrence of cancer and of cancer of the bladder in the young. Hadda²⁰ in an article entitled "Das Blasenkarzinom im jugendlichen Alter (unter 20 Jahren) gives the following. Of 7330 cases of carcinoma involving all locations only 31 or .42% occurred in individuals under 20 and 181 or 2.57% between 20 and 30. Of 5006 cases of carcinoma 48 or .96% were of the bladder and none were under 20 years of age.

In this connection the following from the Massachusetts General Hospital records is of interest. In 129 cases of carcinoma of or involving the bladder, I found one case of adenocarcinoma of the rectum in a girl of 17 which had invaded the bladder secondarily. This of course is not to be regarded as a bladder growth, but is young for the occurrence of cancer.

Another case of primary cancer in a girl of 15 which was described by the pathologist as epidermoid cancer, which I think is of sufficient interest to put on record. She had profuse hematuria for 8 weeks. Cystoscopy showed a sessile tumor on the posterior wall of the bladder the size of a grape. The patient was very anemic, so much so that a preliminary direct blood transfusion was done. This was followed in 3 days by a transperitoneal cystotomy August 2, 1912, with removal of the tumor, including the entire thickness of the bladder wall. She made a good operative recovery. Note one year later, September 24, 1913, says well for 6 months, for last 6 months loss of weight and strength. General examination negative except for 3 months' pregnancy. Cystoscopy showed normal bladder, some urinary frequency. April, 1915, patient states that she went through pregnancy successfully, no trouble except for occasional pain in suprapubic wound.

Between the ages of 20 and 30, I find 2 cases. One a woman of 27 who died 13 days after a curettage of the bladder done as a palliative measure. The pathological diagnosis was epithelioma.

The second was a man of 30 who had an inoperable cancer of the bladder, diagnosis was made by cystoscopy and rectal palpation which showed a hard mass at bladder base. This case is open to doubt as there was no pathological examination, but the case was clinically malignant.

A case of carcinoma occurring at the age of 17 is reported from the Mayo Clinic but no details are given.

It will be seen that cancer of the bladder under 30 is a very rare condition.

On the whole, tumors of the bladder occurring in the young, while fortunately rare, are nevertheless when met with, most unsatisfactory both from the standpoint of diagnosis and treatment.

A STUDY OF KROENIG'S ISTHMUS IN PULMONARY TUBERCULOSIS.*

WALTER C. KLOTZ, M.D., LOS ANGELES, CAL.

THE object of the following study was to determine, if possible, what clinical significance there might be in the disparity of physical signs at the apices as bearing on tuberculous lesions. In studying frozen sections of human subjects, Fetterolf and Norris¹ found a distinct difference in the apices of the lungs, the right being regularly less developed. They concluded that this difference was due to encroachment of the large blood vessels of the neck and the relation of the trachea. They found moreover that this difference occurred in both right and left handed individuals and in the absence of any discoverable pathological changes in the lungs. It seemed of interest therefore, to make a special study of the physical signs at the apices in the presence of tuberculous lesions, keeping these anatomical differences in mind, for the reason that more or less diagnostic significance has been ascribed to disparity of physical signs, especially that of the apical percussion fields. The literature of the subject is probably so familiar as to make the citing of references superfluous. It might be of interest, however, to recall that Bonney² mentions instances where the apical percussion field on the right side was distinctly contracted without any discoverable tuberculous changes on that side. It might be pertinent to refer here also to Kroenig's later views regarding nasal obstruction and consequent "collapse induration"³ as a cause of altered physical signs at the apex.

The material for this investigation consisted of 129 clinical cases admitted to the Barlow Sanatorium since May, 1913, and of 21 controls, with four exceptions pupil nurses who had been examined carefully as a matter of routine when entering upon their service at the sanatorium.

* Read before the clinical section of the National Association for the Study and Prevention of Tuberculosis, held at Seattle, January, 1915.

In the case of the pupil nurses it would be safe to assume that they were well on admission to the training school of a general hospital. They had moreover been able to perform their duties for a period of one year or more without impairment of health. They cannot be accepted as absolute controls, naturally, for the reason that a previous infection with tubercle bacilli cannot be positively excluded. Those in whom a tuberculous implantation seemed at all probable were not considered.

In making these studies, the determination of Kroenig's isthmus was selected as the index of any existing disparity, because the difference could be recorded graphically and the figures in centimeters noted on the case charts. In this way the results obtained in a series of cases could be tabulated more readily, for the sake of comparison. Kroenig's method was given preference over Goldscheider's because of less difficult technic and consequent greater accuracy. The measurements in the clinical cases were all made at the time of the first physical examination after admission. The area of transmitted pulmonary resonance was outlined with skin pencil as far as the clavicle in front and the spine of the scapula behind. These outlines were transcribed as accurately as possible on the case charts and the actual measurements in centimeters noted. In those cases where on account of considerable retraction of the apex the isthmus was obliterated and the area of pulmonary resonance did not reach the border of the trapezius muscle, the isthmus was noted as "O," regardless of the highest point at which pulmonary resonance could be noted.

For the sake of convenience in studying the results, the cases were divided into groups. The first group comprises cases with predominant right sided lesions, the second group, cases with predominant left sided lesions, and the third group cases with more or less extensive bilateral lesions. Taking up the first group we find that out of 44 cases with predominant right sided lesions, the isthmus was narrower on the right side in 43. In three cases there was complete obliteration of the isthmus on account of retraction of the lung. In 18 cases with predominant left sided lesions the isthmus was narrower on the left side only in 4, and in these there was retraction of the lung with complete obliteration of the isthmus on account of extensive cavity formation. The third group composed of 67 cases with lesions distributed fairly equally over both sides showed narrowing of the isthmus on the left side only in one case, here due to an old fibrous lesion. We find, therefore, that out of 129 clinical cases the isthmus was narrower on the right side in 123 or 95.35%.

Among the 21 controls we find a narrower isthmus on the right side in 18 or 86.6%. On account of the disproportion of controls to clinical cases these results must be interpreted carefully.

Of the series of clinical cases four died at the sanatorium and came to autopsy. It will be of interest to compare the clinical findings with the anatomical changes and to study the relation of both to the physical signs at the apices. In order to bring out these features more distinctly, the autopsy findings in these four cases have been considered more in detail.

CASE 1. No. 613. Isthmus right side 2.5 cm.; left 5 cm. *Clinical Diagnosis:* Disseminated general military tuberculosis; chronic tuberculosis with cavity, right apex. *Necropsy:* anatomical diagnosis; disseminated military tuberculosis both lungs; chronic tuberculosis both upper lobes; left apex fibrous nodule retraction and puckering of pleura, adhesions; disseminated military tuberculosis upper and lower lobe. Right lung: disseminated military tuberculosis upper and lower lobe; fibrocaseous consolidation apex with medium sized multilocular cavity, adhesions and thickening of pleura.

CASE 2. No. 641. Isthmus right side 4 cm.; left side 7 cm. *Clinical Diagnosis:* Fibrocaseous tuberculosis both lungs, extensive thickening and adhesions of pleura; cavity right apex; cavity or recent consolidation left upper. *Necropsy:* anatomical diagnosis: fibrocaseous tuberculosis involving nearly all of both lungs. Left lung partial consolidation of upper lobe, with three areas of marked consolidation, no cavities, no adhesions. Right lung: dense adhesions, fibrocaseous tuberculosis consolidation of upper lobe, with medium sized multilocular cavity at apex; marked infiltration of lower lobe, with fresh area of consolidation and two small cavities.

CASE 3. No. 648. Isthmus right side O, left side 5 cm. *Clinical Diagnosis:* Fibrocaseous tuberculosis right upper lobe with cavity, infiltration right lower lobe; infiltration and partial consolidation of left upper lobe. *Necropsy:* Anatomical diagnosis: Left lung, fibrocaseous consolidation apex, small cavity, old adhesions; lower lobe, infiltration and small fibrous nodule near apex. Right lung, extensive adhesions, markedly thickened pleura, fibrocaseous consolidation, upper lobe, marked induration apex, medium sized cavity, showing fibrous wall and trabeculation; fibrocaseous consolidation, middle lobe and apex of lower lobe, with small cavity, lower lobe.

CASE 4. No. 696. Isthmus right side O, left side 4.5 cm. *Clinical Diagnosis:* Fibrocaseous tuberculosis both lungs; cavity both apices. *Necropsy:* anatomical diagnosis: fibrocaseous tuberculosis involving nearly all of both lungs. Left apex large multilocular cavity, adhesions and thickening of pleura. Right apex; large multilocular cavity, adhesions and thickening of pleura.

A study of the autopsy findings shows therefore, that although in all of these four cases there were distinct lesions at the left apex, there was not a corresponding change in Kroenig's Isthmus on the left side.

The findings in both the clinical cases and autopsies would justify the belief, therefore, that in most instances the differences in measurements of the apical percussion fields could not be due to tuberculous changes alone. It would

be difficult to explain the almost constant narrowing of the isthmus on the right side regardless of the side of more extensive lesions. It may be granted that implantation does occur more frequently on the right side, at or near the apex. Some of the causes for this predisposition have been cleared up by Baemeister's experiments upon animals. It is only reasonable to assume that some changes at the right apex are the result of former tuberculous implantations, the lesions having become healed, and being no longer active at the time of observation. If this were true however in all cases, we ought to meet with corresponding changes more frequently on the left side than we do, especially in the presence of more extensive or predominant lesions on the left side. It is exceptional to find lesions limited to the right side in active cases, (in our tabulations the cases were classified only as to predominant lesions), infection usually extends to the left side quite early in the course of the disease and greater portions of the left lung may become involved while the process on the right side may become quiescent or fully arrested. Under such circumstances it would be reasonable to expect changes at the left apex more frequently, assuming that such changes do occur secondarily as a result of tuberculous inflammation. It is to be noted also that the disparity of the isthmus was no more frequent relatively in open active cases than in active, and only slightly more frequent than in controls. It is only in cases with very extensive lesions and marked contraction of the lung that there was a corresponding narrowing of Kroenig's isthmus on the same side.

TABULATION OF RESULTS OBTAINED FROM MEASUREMENT OF KROENIG'S ISTHMUS IN 129 CASES OF PULMONARY TUBERCULOSIS AND 21 CONTROLS (NORMAL INDIVIDUALS).

		ISTHMUS NARROWER		ISTHMUS SAME	
		Right Side.	Left Side.	Both Sides.	
Cases with right-sided lesions	44	43	1	0	
Cases with left-sided lesions	18	14	4	0	
Cases with bilateral lesions	67	66	1	0	
Total number of cases	129	123	6	0	
Controls (normal individuals)	21	18	1	2	

NOTE: Among the controls the difference in measurements of Kroenig's Isthmus varied from 0.5 cm. to 4 cm.

In view of our findings the conclusion might be drawn therefore: that unless the disparity of the apical percussion field, as expressed in terms of Kroenig's isthmus is very marked, it does not necessarily point toward tuberculosis of the corresponding side; that such disparity is also of much less significance on the right side than it is on the left; and that in most instances the disparity of the apical percussion fields is simply due to anatomical changes, unrelated to tuberculosis.

INTUSSUSCEPTION.

By WILLIAM E. LADD, M.D., F.A.C.S., BOSTON.

WITHOUT prompt surgical intervention, intussusception is one of the most fatal diseases of infancy and one to which perhaps enough attention has not been paid in this community. The history of the Children's Hospital in connection with this disease is very instructive and interesting.

Prior to 1908, this hospital had had eight cases operated on with one recovery. At the same date, at the Infants' Hospital, there had been eight cases with one recovery, and at the Massachusetts General Hospital, ten cases of infantile intussusception with one recovery. These figures show clearly two striking facts; one, the remarkably small number of cases referred for surgical aid in this community, and the other, the high mortality.

Since 1908, however, the situation has changed slightly. There have been in the Children's Hospital sixty-three cases operated on. Of these, thirty-two have recovered, and thirty-one have died, giving a mortality of just under 49%. Of the last nineteen cases operated on, fifteen have recovered and four have died, showing a mortality of 21%.

This is a considerable improvement to have taken place in seven years, but there is still room for more. But perhaps more striking still are the figures showing the mortality of the operation when performed at a varying number of hours after the onset of symptoms. In this series of sixty-three cases there were four cases operated on at the end of twelve hours with no mortality; eighteen cases operated on at the end of twenty-four hours with three deaths, a mortality of 16.66%; thirteen cases operated on at the end of thirty-six hours with three deaths, a mortality of 54%; and seventeen cases operated on after sixty hours or more show two recoveries and fifteen deaths, a mortality of 88%. (See Chart I.) Bearing these figures in mind, it is obvious, that the most essential requisite for avoiding a high mortality is to make the diagnosis early and resort to operation at once. To make an early diagnosis in intussusception is not as a rule a difficult thing to do providing one is on the lookout for it.

In this series of sixty-three cases, forty-nine occurred during the first year of life; eight during the second; and the remaining six were scattered between the ages of three and nine. One

should be most on the "qui vive," therefore, in infants under two years of age. Another fact to be borne in mind is that intussusception occurs much more frequently in healthy and well nourished babies than in those that are poorly developed and nourished. Occasionally the bowel invaginates in the course of an infectious diarrhoea or during purpura; but such cases are the exceptions, not the rule, and one should remember to be most expectant of finding intussusception in a healthy baby under two years of age. In making the diagnosis, particular attention should always be paid to the parent's story, which in our experience and in that of other surgeons in various parts of the world, is very typical. The mother will usually say that the baby having been perfectly well was suddenly taken with an attack of pain, turned pale, and soon afterward vomited. Following this the baby had periods of apparently being almost well, varied by attacks of pain with crying out and drawing up the legs. A normal looking stool was then passed but after five or six hours a stool composed almost wholly of blood was passed and the baby vomited several times and refused all food. A story of this sort is almost sufficient data for a diagnosis of intussusception. But it is extraordinary how often we still receive babies who have had this typical story and for whom the doctor called has ordered a dose of castor oil or other cathartic and assured the mother the baby would

be all right in a day or two. The baby, of course, gets progressively worse and comes to us in *extremis* at the end of two or three days. The only way I can explain this happening so frequently is that during the first twelve to twenty-four hours, these patients look perfectly well, except during their paroxysms of pain, when peristalsis is active trying to push the mass along. If the doctor sees a healthy looking baby between pains and does not pay sufficient attention to the mother's story and does not make a careful examination, he will necessarily miss the diagnosis and by delay remove the best chance for the baby's recovery. During the first twelve hours the physical examination of the abdomen will reveal a mass in the right lower quadrant, under the right costal border in the mid-line at the level of the umbilicus, or in the left upper quadrant according to how far the bowel has invaginated. At this period of the disease the mass is usually easy to feel, owing to the fact that little distention has developed. The mass is usually slightly movable, which is its most typical feature, its size and shape being dependent upon the amount of bowel invaginated and varying considerably. The only time when the mass is hard to feel is when it is situated under the right or left costal border at the end of thirty-six or forty-eight hours, when there is marked distention present. In such cases the x-ray has a limited field of usefulness. After bismuth injection, the intussusceptum will show as a cervix-like projection into the bismuth in the colon below it. Later on when the mass has progressed to the sigmoid or rectum, it has attained such large proportions that it is easy to feel either by abdomen or by rectum in spite of much distention.

It is now after forty-eight hours that the baby's signs and symptoms correspond with the description given in the older text-books of medicine and surgery. The sunken eyes, the distended abdomen, the mass in the rectum, etc. If one waits for these signs, one has waited until the baby's chance for recovery has disappeared.

As to the operation: The incision should be made over the right rectus when the tumor is in the right side of the abdomen. When the tumor is in the left of the abdomen, the incision should be made in the mid-line and run high enough above the umbilicus to enable one to reach the hepatic and splenic flexures easily. The mass having been located, reduction is commenced intra-abdominally by pushing back the advancing point between the middle and forefinger. This is continued as far as it goes easily, when the mass is delivered into the wound and the reduction continued extra-abdominally. The last part of the reduction is always the most difficult, usually due to oedema. By pressure on the tumor, the oedema can frequently be diminished sufficiently to allow the completion of reduction in a case that appears at first hopeless. Adhesions, frequently spoken of as preventing reduction, as a matter of fact very rarely exist. Clubbe,

who has had perhaps as large an experience as anyone with this disease states that he has never seen any real adhesions. I have seen in one case in which I performed a resection very dense adhesions, but that is the only time I have ever seen any. Oedema, gangrene, and swelling of the mesenteric glands are the three conditions which sometimes makes reduction impossible. In such cases resection has to be resorted to, but when this becomes necessary the hope is forlorn. Clubbe reports one or two successful cases and there are one or two others in the literature. We have never had a successful case here, though several have withstood the operation well only to die a day or so later from a pre-existing toxæmia. The after-care consists in combating shock, irrigation of the colon to reduce toxæmia and proper feeding started soon after the operation.

In any given community where cases are brought to the surgeon late, that surgeon is bound to have a high mortality. The chief problem then, is to educate the general practitioner to be on the lookout for this disease, which is not so rare as has been supposed; to appreciate the signs and symptoms of the disease in its early stages and send the case without delay to a surgeon of experience in the surgical diseases of children. When this is accomplished, the high mortality of the past will be eliminated.

Clinical Department.

SOME UNCOMMON TYPES OF SKIN DISEASE.

By A. J. NUTE, M.D., BOSTON.

*P. A. Surgeon, U. S. Public Health Service,
Immigration Station, Boston.*

ONE of the best places in the world to see various types of skin disease is in the medical examination of arriving aliens. People coming from all quarters of the globe, often in anything but clean condition, may be found afflicted with many of the diseases not often seen in private practice.

A dermatologist in New York once said in a lecture that dermatology was one of the hardest of specialties, as there were about two hundred skin diseases classified by various authorities and in practice about two thousand modifications. The more one deals with immigrants the more one is inclined to agree with that statement.

The five cases given were selected as being of more interest to the general practitioner than the specialist, for the diseases may be found at any time in the country as well as in the city. The specialist having connection with a large clinic drawing its trade from all walks of life and all races has an opportunity to see cases that would

be so rare as to puzzle his brother in general practice.

CASE 1. Favus of the body. Greek, male, 19 years of age. Scalp negative; finger nails infected and his body in general from shoulders to feet. Favus is a peculiar disease. Recognized as contagious, yet often selecting certain areas and allowing other parts of the body to escape. If the scalp is infected one should look over the finger nails with care and vice versa, as it is usually found in a class of people who do not consider it impolite to scratch their heads at any time or in any place. Nevertheless, it is often found in the head and the nails free. To find it over the body I believe to be rare. This case evidently started in the hands and was one of the unusual cases that spread over the parts of the body protected by clothing and left the scalp free. Later this case developed symptoms of intestinal irritation due to the achorion *Schönleini* getting into the rectum.

CASE 1. FAVUS.

CASE 2. Blastomycosis fungoides. Native of Poland, between 25 and 35 years of age, laborer; in general, well developed and nourished. Both hands and elbows involved. On first examination this case closely resembled either verrucous tuberculosis or vegetative syphilide. Under the microscope, the true nature appeared in the large number of yeast plant fungi present. The lesion presents very little pus, being mostly scar tissue and crusts. The violet or lilac color described by many writers was missing in this case.

Why certain yeast and mould fungi are pathogenic and others harmless is a problem; also whether

they differ in some way from the ordinary varieties. While these cases often seem to be in otherwise good physical condition, sooner or later it is common to find constitutional symptoms of either tuberculosis, pyaemia, necrosis of bone, subcutaneous abscesses or subcutaneous nodes resembling erythema multiforme.

CASE II.

CASE 3. Pityriasis rosea. Russian Hebrew, male, 26 years of age, tailor, arrived in Boston on an Italian ship. A very worried man, shunned by the other passengers in the steerage and as a precaution kept in the ship's hospital. Various people had told him he had either syphilis or some other loathsome contagious disease, and when the patient came up for examination he was ready to believe the worst, broken out from his shoulders to feet with pale red, irregularly sized, slight-scaling efflorescences. These cases are not uncommon in the larger city clinics but must also exist in other places and might easily be treated for some more serious condition.

A few weeks treatment with weak sulphur ointment resulted in a well and happy man.

CASE 4. Pellagra. Portuguese male, 58 years of age, laborer, resident of Massachusetts for 25 years.

CASE II.

CASE III.

Pityriasis rosea, showing different size and development of lesions.

History of the disease about six years' duration, worse in the summer than in the winter. In the literature one may find the statement that the disease exists south of the 41st degree of latitude, but here is a case that evidently arose in Massachusetts, and in the future we shall hear of more, regardless of climate. The three D's were characteristic, diarrhea, dermatitis, delirium, in addition to marked muscular weakness. As one of his relatives aptly described the case, "He seems to get sun burned in the spring and then has this trouble. Toward fall it begins to get better, but he cannot work."

CASE IV.

CASE 5. Vitiligo. Portuguese female, from the Azores Islands, 62 years of age, housework, and never in the United States before August, 1915.

This case was thought worthy of showing, not so

CASE V.

much as uncommon as because of the unusual bilateral symmetry of the lesions. This condition has existed over twenty years with no apparent cause and the woman was otherwise healthy for her age.

Another interesting fact with such cases is that

it has been reported on good authority that in certain regions of Asia they are segregated and kept with lepers. As vitiligo shows no areas of anesthesia, no structural changes in the skin or constitutional symptoms as in the case of leprosy, it hardly seems that the two conditions are likely to be confused. Possibly these cases are held only temporarily as suspects.

CASE V.

Medical Progress.

PROGRESS IN BIOCHEMISTRY.

BY A. EVERETT AUSTIN, M.D., BOSTON.

CARBOHYDRATE METABOLISM.

BASED upon experimental consideration, A. I. Ringer¹ has come to the conclusion that hydroxybutyric acid remnants cannot possibly become oxidized to the ketone stage, the form in which it circulates, because oxidation can be accomplished only by the removal of two atoms of hydrogen, and in this compound there is only one available hydrogen atom. Therefore the ability of glucose to check acid intoxication in the normal individual is based upon its ability to unite with that acid and therefore change its structural configuration so as to give rise on further oxidation to non-acetone genetic products. Hence in the sufferer from diabetes, since both glucose and hydroxybutyric acid circulate in abundance in his blood, the important influence in acidosis is probably the failure of that individual to bring about this glucoside union. Hence it seems probable that the failure to accomplish this synthetic condition is at the bottom of all chemical disturbances in the diabetic, such as the loss of glycogen formation, with the consequent hyperglycemia, inability to burn glucose and the disturbances of the oxidation of the lower fatty acids, since all can be explained by the presence of this deficiency.

Frank P. Underhill,² working on a different line of research and endeavoring to explain the well known fact that suitable quantities of hydrazine salts, administered subcutaneously, induce marked hypoglycemia, with the accompanying reduction in the glycogen content of the liver, has analyzed the blood, liver and muscles of dogs so treated, with results which show clearly that the transference of the body carbohydrate and glycogen to the muscles does not suffice as an explanation of the disappearance of this substance from the liver and the decreased blood sugar content. On the other hand, there are indications, not only that the liver is deprived of this glycogen, but that the muscles also suffer to the same extent, leaving no explanation for the ultimate fate of the disappearing sugar. At least with hydrazine, in distinction from phlorizin, no sugar ever appears in the urine.

Continuing this investigation further, the same author, after subcutaneous administration of hydrazine to rabbits, perfusing the heart with sugar-containing fluids, found no greater loss of sugar with such animals than with those to which the drug had not been given; the problem of the fate of the sugar still remains unsolved.

The effect of inulin on the output of glucose in diabetes has been investigated by Lewis and Frankel,³ who have shown by experimental evidence that inulin administered to phlorizinized dogs gives rise to no glycosuria. The effect of levulose on the dog and similar animals is the elimination of a large amount of glucose. Since levulose administered to such dogs is largely excreted as glucose and not levulose, there seems little probability that any appreciable amount of inulin is converted to levulose or to any product which can give rise to glucose in the diabetic organism.

Epstein and Bachr⁴ have investigated the subject of hyperglycemia following hemorrhage which has been previously attributed to the psychic influence, the so-called emotional glycosuria. These authors, however, have discovered that the increased sugar of the blood is a compensatory response on the part of the organism to keep the total blood sugar up to the level commensurate with the needs of the tissues. On account of the diminished blood volume it is accomplished by the increase in the concentration. Similarly, if the total volume of fluid in circulation is not diminished, and when the blood is withdrawn, it is replaced immediately by saline solution, the procentual concentration of the diluted blood rapidly rises to what it was before the removal. In other words, the total sugar in the circulation remains unchanged. We may have both absolute and relative hyperglycemia, and the glycogen only increased when the hyperglycemia is absolute. There is also a possibility that this observation may account for some of the so-called cases of renal glycosuria; such glycosuria might have been dependent upon

an increase of the total blood sugar, and the absence of any procentual increase could be accounted for by the abnormally large blood volume. Hence, in the study of diabetes mellitus it is necessary not only to determine the percentage of sugar in the blood, but also, as far as possible, the total amount of blood in circulation.

Recognizing the fact that the thyroid and parathyroid exert a marked influence on the elimination of sugar as well as metabolism of carbohydrates, Underhill and Blatherwick⁵ have pursued their investigations upon dogs after thyroparathyroidectomy, and soon learned that the average amount of blood sugar following this operation is always low. The reduction begins before there are any convulsions, therefore their conclusions are that hypoglycemia following this operation is neither the cause nor the result of the accompanying tetany, for, although dextrose injections restore the blood sugar to its normal content, they have no effect on the convulsions.

It is therefore suggested that the removal of the thyroid and parathyroid gives rise to two distinct effects, the first being manifested upon the blood sugar regulating mechanism, causing hypoglycemia, the other upon the nervous system, producing tetany. Continuing this investigation, the same authors have shown that calcium is intimately associated with both effects, for injections of calcium lactate will temporarily restore the blood sugar to normal and also abolish tetany temporarily. Furthermore, calcium lactate may play an important part in maintaining the equilibrium of the volume regulating mechanism during normal life.

This subject of the effect of the removal of the parathyroid, the relation of the parathyroid to sugar tolerance and the effect of calcium salts has also been studied by Marine,⁶ who reports that in eight of the ten cases under consideration a marked fall in sugar tolerance was noted after parathyroidectomy, while in two with natural low tolerance limits, the tolerance remained unchanged after the removal of at least three parathyroids. The feature of most interest is that parathyroidectomy does not result in constant glycosuria, nor does the administration of calcium salts seem to modify the altered sugar tolerance of parathyroidectomy.

PIGMENTS OF MILK FAT.

For a number of years a great variety of yellow animal pigments has been given the general term of lipochrome, which recent investigations have shown, bear in many instances a close chemical relation, or rather possibly are identical with the carotin, or the yellow pigment of plants.

Palmer and Eckles⁷ have continued this investigation with the following results: The fat of cow's milk is indebted for its natural yellow color to the pigments, carotin and xanthophyll, especially the former, which is a well known

yellow vegetable pigment found accompanying chlorophyll in all green plants. Furthermore, these pigments of milk fat are not synthesized in the cow's body, but are merely taken up with the food and consequently excreted in the milk fat. This is demonstrated by the fact that when cows during the winter receive food poor in these pigments, the total fat, while not necessarily diminished in amount, approaches a colorless condition, increasing with the length of time they are deprived of these pigments in the food, which apparently proves that there is an accumulated store of pigment in the organism of the cow. When, on the contrary, the animal is fed, after this period of restriction, with fresh food, of which green grass contains the greatest portion of pigment, the color immediately returns to the milk fat. Continuing this investigation, they have demonstrated that the yellow lipochrome of the body, corpus luteum, skin and the secretion of the cow, like the yellow pigment of butter fat, are composed principally of carotin, which may have sometimes associated with it some of the lesser yellow pigments. It has been further found that the yellow pigment of the blood serum of the cow is also composed principally of carotin, the widespread hydro-carbon pigment of plants. On the contrary, the blood serum of the new-born calf is free from these pigments. Hence the serum pigment is probably of greater importance in the form of milk fat, body fat and corpus luteum of the cow.

Applying this investigation to humans, the same authors found that the fat of human milk may be tinted by carotin and xanthophyll, the same pigments which characterize the fat of cow's milk. The relative proportion, however, of carotin and xanthophyll, in human milk fat, is much more nearly equal than in the fat of cow's milk. While the colostrum fat of the former is characterized by the same high color as is the fat of the milk of cows, the pigment of the human body fat is identical with the pigment of the milk fat.

In conclusion, by experimental evidence these authors have shown that there is a very close relationship, if not identity, existing between the yellow pigment of milk fat and the urochrome of the urine. For these have the same chemical reaction, showing no lines in the spectroscope. Both can be converted by acetaldehyde into pigments having spectroscopic qualities which are identical with urochrome.

UREA.

Marshall and Davis⁸ have pursued certain investigations to determine the urea content in various tissues of the animal body and the relation of its percentage to that of blood, by the analysis of the tissue before and after injections of large amounts of urea; similarly, analyses of animals whose kidney functions had been interfered with, either with or without the urea in-

jections and from autopsies of nephritics. Their conclusions are that urea is present in all the organs and tissues of normal animals and the urea is approximately uniform with that of the blood, both in normal conditions and when abnormally large amounts of urea are circulating. When urea is injected subcutaneously it circulates to all parts of the body in a very few minutes. The urea is eliminated with great rapidity by the kidneys, with such rapidity that excretion may rise to 16 grams per kilo of body weight per day, and even higher. The rate of urea in normal animals is directly proportional to the concentration of urea in the blood; when the excretion of urea is prevented, the entire amount formed is stored in the body. There is no evidence of its conversion into any other substance.

Fiske and Sumner⁹ have engaged in an investigation to determine the chief site of urea formation in the body from amino acids. It has always been conceded that the liver represents the chief site of urea formation. This has always been open to question because experiments have been only indifferently controlled. The conclusions of these authors, based upon a large amount of experimental work, are that unassailable evidence of the liver's chief part in urea formation from amino acids does not exist. The accumulation of urea per unit of mass in the blood and tissues with intravenous injections of amino acids is as great when the liver and other abdominal organs are excluded from the circulation as when they are in their normal relations. The authors fail to inform us where this transformation takes place.

McLean and Selling¹⁰ have continued the investigations initiated by Folin and Denis on the urea and total non-protein nitrogen in normal human blood. Their conclusions, based upon these investigations, which comprise nine individuals, showed that from 10-23 mgms. of urea nitrogen were found in 100 c.c. of blood, while the total non-protein nitrogen varies from 23-36 mgms. in the same individuals. Hence the concentration of total non-protein nitrogen and that of urea in normal human blood is not constant, but varies within wide limits, according to the various factors,—diet, amount of fluid, etc. Furthermore, there is a close parallelism between the concentration of urea in the blood and the amount excreted in the urine in normal individuals under average conditions. Ambard's coefficient, when computed from results obtained by the method of Folin, varies only between comparatively narrow limits, and may be regarded as constant. In addition, a concentration of the protein nitrogen as high as 22 mgms. per 100 c.c. of blood does not indicate any disturbance in urea elimination unless associated with the relative decrease in the amount excreted. Ingestion of urea does not materially alter the value of Ambard's coefficient, providing sufficient time is allowed for absorption before the examination is made.

ENZYMATIC ACTIVITIES.

As alcohol is used so commonly for the preservation of all pathological specimens and, as it is well known that autolysis rapidly takes place in such tissues, unless strongly inhibited, from the inherent digestive ferment, Wells and Caldwell¹¹ have investigated the strength of alcohol necessary to prevent such disintegration. They found that for complete suppression of the autolytic digestion of liver tissue by alcohol, the actual strength of the fluid added cannot be safely less than 90%. Between 80 and 90% self-digestion may take place, and below 80% of the alcohol autolysis is certain to take place at either room or incubator temperature. For each gram of finely ground tissue at least 10 c.e., or better, 15 c.e. of 96% alcohol must be used for preservation. If such changes are to be fully inhibited this can be more readily accomplished, when not contraindicated, by boiling the tissue a few minutes in alcohol to destroy these enzymes.

As is known, the soy bean contains a very active enzyme which splits urea into ammonium carbonate. This action is specific in that it does not attack any other constituent of the urine.

Van Slyke and Cullen¹² have endeavored to add to our knowledge of this urease and to determine whether it acts by direct contact or by the formation of an intermediate labile compound. If the former were true, the reaction velocity, enzyme concentration being kept constant, should increase in direct proportion to the urea concentration; if the enzyme acts by formation of an intermediate compound with the urea, however, one would expect conditions to be different. So long as sufficient urea were present to keep all the enzyme combined and therefore acting, the presence of excess urea beyond this point would not accelerate the reaction. The excess urea would remain inert, awaiting an opportunity to combine with the enzyme.

As a result of extensive experiments they found that there is actually formed an intermediate compound which acts upon urea.

The former author, Van Slyke, in collaboration with Zacharias, has also studied the influences which retard the action of urease. Such retarding agents were found to be, first, ammonium carbonate, one of the resultant compounds of urea disintegration, which acts largely by increasing the alkalinity of the solution in which enzymatic action takes place. Neutral salts, phosphates and sodium chloride, retard the action of this ferment.

Urea therefore shows its highest activity in the presence of the lowest concentration of phosphates that maintains neutrality. Furthermore, glucose retards enzyme reaction in the same way as neutral salts, an action which is equalled by alcohol in 30% concentration.

Crohn and Epstein¹³ in investigating the influence of normal and diabetic serum on pan-

creatic amylase, found that even the smallest quantities of serum had a marked stimulating effect on the amylolytic activity of the extract of a dog's pancreas, this increase amounting often to three and fourfold. This power is not diminished by boiling the serum nor by allowing it to remain at 28° C for many hours. This activating power of the serum is lessened by dialysis, while the salts of the serum and the proportion in which they exist in it are largely responsible for this phenomenon.

Sodium chloride has no effect; adrenalin may have a slight positive influence, while lecithin has none. These facts are of great interest because of the duodenal content which, for the amylolytic activity, seems barely sufficient to digest the ordinary daily intake of carbohydrate, but if we increase this power to two to four times by the presence of serum salts, we can satisfactorily explain why starch so rarely appears in the stools and why pancreatic digestion so rarely becomes insufficient for carbohydrate.

Joblin and Petersen¹⁴ have continued their investigations on ferment inhibiting substances. Their present work is devoted to the agencies which restrict proteolytic enzymes acting in an alkaline medium. The result of these studies is as follows:—

Soaps prepared from olive oil, croton oil, cod liver oil, linseed oil, etc., have the property of markedly inhibiting the action of trypsin and leucoprotease. The activity of these soaps is dependent upon the degree of unsaturation of their fatty acids, and is in proportion to their iodine value. Saturation of the acids with a halogen (bromine or iodine) causes a loss of this property, while soaps of the saturated fatty acids do not possess this characteristic.

The same authors, continuing their investigations, have come to the conclusion that the ferment-inhibiting action of the blood serum is due to the presence of a compound of the unsaturated fatty acids. This conclusion is based upon the fact that when the fatty acid compound is removed from serum, it loses this action and, furthermore, soaps prepared by saponifying the chloroform and ether extract inhibit the action of trypsin also, with a decrease in strength. Anti-enzyme in old sera is probably due to the action of the serum lipase. These experimental results are apparently confirmed by clinical investigations, that is, there is an increase of the serum anti-enzyme in acute infections, such as typhoid, pneumonia, etc.; in chronic wasting diseases such as syphilis and tuberculosis, and in severe anemias such as those accompanying malignant growths; in all but the first of these the demand of the body or the action of toxins causes a marked reduction in the fat deposits of the body. This disappearance of fat, in conjunction with the lowering of the powers of the liver and tissues in general, causes an increase in the unsaturated fatty acids in the blood and thus an increase in the ferment-inhibiting action.

CONSTITUENTS OF THE BLOOD.

Folin and Denis¹² have examined the blood of about two hundred patients at the Massachusetts General Hospital to determine the creatinin and creatin content of the blood, and they have never been able to find any specific creatin retention. They further state that except in extreme conditions of urinary reduction approaching anuria the creatin remains at the normal level. It was found that the human kidneys were able to remove the creatin from the blood with remarkable ease and certainty. The completeness of this excretion is exceeded only by the still more complete removal of the ammonium salts.

Fiske and Karsner¹⁶ have studied the effects of acute destructive lesions of the liver on the ammonia content of the blood. Their object was to learn whether there is any greater interference with the function of the liver in eliminating ammonia, when larger areas were destroyed than is known in human sclerosis. It is probable that the factor of safety in the liver is so great that no such alteration of function occurs *a priori*, at least when the amount of destruction is compatible with life and the results of the experiment were in accordance with this assumption.

Upon perfusing cat's liver from animals which had been poisoned by chloroform, phosphorus and hydrazine, it was found that, in spite of the marked destruction of liver tissue, the reduction of ammonia in the perfused blood, as a result of one hour's activity, was very marked and, by use of a method of oxygenation, the reduction of ammonia content was still greater. To sum up the results, they declare that there is no difference between normal livers and the livers poisoned by the various toxic substances mentioned, in the result of their ability to lower the ammonia content of the blood perfused through them.

Marriott¹⁷ has made a careful study of the blood in acidosis from the quantitative standpoint, employing a newer method for the acetone bodies, in which quantities of blood as small as 1 to 5 c.c. may be employed. He found, in brief, that the blood of normal human subjects and that of dogs, pigs and cattle contain less than 1.5 mgms. of aceto-acetic acid and less than 4 mgms. of oxybutyric acid per 100 grams of blood, the results being expressed in terms of acetone. In acidosis the acetone bodies in the blood are much higher than normal; the highest degree obtained by this author was 28 mgms. of aceto-acetic acid and 45 mgms. of oxybutyric acid per 100 grams of blood, expressed as acetone.

Shaffer¹³ has again investigated the normal level of blood sugar in the dog. Special effort was made not to arouse pain or fright in the animal bled. The author declares that, based upon twenty different dogs, in some instances bleedings having been made for a period of sev-

eral weeks and under different conditions as regards food and the state of nutrition, the results varied between 0.02 and 0.065%, and these values could therefore be taken as more nearly the normal limits of the blood sugar content of dogs. Of these results, one-half to one-third greater values are accepted as normal. Shaffer's explanation is that the former large amounts found depended upon emotional excitement of the animal, which appears to produce rapidly a temporary hyperglycemia. The author has agreed that the blood sugar of man can be regarded as varying from 0.06 to 0.11%, and declares that this deficiency is due to lack of emotion, because such blood is always drawn from a superficial vein, and without causing pain in the latter.

Jacobson¹⁹ has made a study of the disappearance of ammonia from the blood in normal and in thyroidectomized animals. This has been determined by the rate of disappearance of the ammonia from the circulating blood after intravenous injections of ammonium carbonate. The liver is left in its normal relations, and the factor of elimination of ammonia through the kidney excluded by ligation of the renal vessels.

The conclusions of these experiments are, that with the kidney excluded from the circulation, ammonia injected into the blood is so rapidly removed that only a very slight excess is present five minutes after the injection.

There is only a very slight difference between the amount of ammonia removed in normal and thyroidectomized animals. Furthermore, this method is not adequate for the determination of liver efficiency (ammonia destroying power), because the rate of disappearance of excess of ammonia from the blood, independent of the liver function, is so great as to render the ammonia destruction of the liver almost a negligible quantity.

Karsner and Denis²⁰ have continued their studies on nitrogen retention in the blood in experimental acute nephritis and have demonstrated that arsenic nephritis shows almost no retention of nitrogen, although studies of urinary nitrogen indicate an increased catabolism. Diphtheria nephritis also, in its early stages, as the former, shows little or no actual nitrogen retention in the blood. In both cases, however, there appears to come a time when the excreting power of the kidney is exhausted and nitrogen accumulates in the blood.

While both the former produce tubular changes, tartaric nephritis shows changes which are more of a glomerular character, and in this form there is the most remarked retention of nitrogen in the blood. This persists even though the glomerules show almost no change and continue to clear up with the progress of time.

ABNORMAL METABOLISM.

Levene and La Forge²¹ have continued their studies on the pentose of the urine of an indi-

vidual, apparently in good health, by means of obtaining a large amount of the osazone from which they determined that this sugar belongs to the xylose group. This conclusion is based upon certain indirect evidence, such as the increase of its optical rotation on standing and, upon distillation with hydrochloric acid, the sugar content produced a large quantity of furfural; that by oxidation experiments the uric pentose has the structure of a keto pentose.

Raiziss, Dubin and Ringer²² have made some special studies in endogenous uric acid metabolism in cases of psoriasis; based upon inconclusive evidence, persons affected with this disease have been supposed to have an abnormal metabolism of uric acid, but these authors considered such patients normal as far as uric acid metabolism is concerned because the various stages of the disease did not seem to vary the uric acid excretion in any way. However, in the course of these studies, it was found that these patients improved remarkably when kept on a meat-free, low protein diet. Their summaries in conclusion are that the uric-acid elimination, based upon ten individuals was much lower than was previously reported in the latter. Furthermore, different individuals under the same conditions of diet and rest, eliminated practically the same amount of uric acid per day, which is increased equally by work and high protein intake.

On placing these individuals on a practically nitrogen-free diet, which was at the same time free from nuclein, after the vegetable diet period, the uric acid amounted to about half of what it was on the vegetable diet (0.040 grams per day). Finally on giving milk, eggs and zwieback to the extent of 12 grams of nitrogen per day to one of these patients immediately following the nitrogen-free diet, the uric acid output rose but slightly (0.05 grams per day), but when the vegetable diet was resumed, the uric acid nitrogen elimination rose again to its former level (0.44 grams per day).

Bergeim, Stewart and Hawk²³ have made some careful investigations of the metabolism of calcium, magnesium, sulphur, phosphorus and nitrogen in acromegaly. The patient was a young male, a native of Russia, who presented all of the characteristics of this peculiar disease. Their conclusions are, that there is a distinct retention of calcium, magnesium and phosphorus, which is unaccompanied by corresponding changes. In general, metabolism is normal, as evidenced by a practical balance of nitrogen and sulphur. It is, therefore, concluded that there is a primary disturbance in the metabolism of the mineral elements mentioned with the probable formation of new bony tissue. The distribution of elements between urine and feces shows no abnormal variations.

The same authors have prosecuted a similar study in calcium metabolism after thyroparathyroidectomy. The patient, on account of the difficulty in respiration, had had first a trache-

otomy and then the removal of the entire thyroids as well as the parathyroid glands. The patient on account of his condition was fed upon a fully liquid diet. There was found but slight retention of calcium during a ten-day period. The urine excretion was as low as 0.013 grams per day on a daily ingestion of 1.673 grams of calcium. During this period, however, but slight increase was observed in the calcium content of the blood. No symptoms of tetany were discovered in the patient who survived the operation thirty-nine days. The low urinary and blood calcium values are taken to show deficient absorption of calcium, which may bear some relation to the decreased gastric secretion after parathyroidectomy. The non-occurrence of tetany was considered due to the high calcium intake and to the development of a compensatory mechanism in which the pituitary body may play a part.

CASES OF INFECTIOUS DISEASES reported to the Boston Board of Health for the week ending Nov. 23, 1915: Diphtheria 61, of which 11 were non-residents; scarlatina 43, of which 10 were non-residents; typhoid fever 9; measles 51; tuberculosis 54, of which 2 were non-residents. The death-rate of the reported deaths for the week was 14.04.

Harvard Medical School

MEDICAL EXPERT TESTIMONY AND LEGAL LIABILITY.*

Mr. JOHN LOWELL presided and outlined the two subjects for discussion.

Mr. JUSTICE HAMMOND of the Supreme Court of Massachusetts: The difficulties of the doctor in court are admittedly great, owing especially to the form of procedure known as the "hypothetical question." Failures on the part of doctors as witnesses are of two general classes:

- (a) The doctor fails to realize how completely his reputation depends on his honesty in court. Further, he does not understand his relation to the lawyers who employ him.
- (b) The doctor allows personal theory or a desire to be consistent to give his statements an inexcusable bias.

Mr. WILLIAM G. THOMPSON:

A. *Evidence.* The essential differences between the legal and the medical point of view are:

- (a) Unlike science, the practice of law deals with practical controversies and is, therefore, not disinterested and impartial.
- (b) The determination of justice not being assigned to witnesses or advocates,
 - (1) Witnesses are responsible only for answers to questions.
 - (2) It is a violation of advocate's duty to advance evidence against his client's case.

B. *The Special Province of the Expert Witness* becomes evident by noting:

- (a) Ordinary witnesses are expected to give facts without any inferences.
- (b) Expert witnesses are expected to give the facts *plus* such inferences as their special training warrants them in making.
- (c) Expert witnesses may even give such inferences as they are qualified to make from facts outside their own experience.

C. *The Doctor's Legal Responsibilities as a Witness.*

- (a) *Diagnosis.* Here the attending physician is usually responsible. Caution against being deceived by patient's conduct during convalescence. Doctor thus becomes witness to nothing but his own credulity.

(b) *Prognosis.* The court is concerned not with what is possible, but with what is probable.

(c) *Causation.* The court is concerned only with immediate real and substantial causes. Remember two facts: (1) There is a difference between *post hoc* and *propter hoc*. (2) The intentions of the agent are of no import in the actual causation.

D. *Two Essentials of Preparation of Case are*

- (1) In conference with the lawyer before the trial the physician should ask and find out definitely what questions he is to be asked. If these questions cannot be answered honestly to the satisfaction of the lawyer, this is the time to withdraw from the case.
- (2) Review all your reasons for thinking as you do.

E. *Conduct in Court.*

- (a) No one is allowed to take away a witness' right thoroughly to understand a question before he answers it. If in a hypothetical case expert desires further data, he may ask for them.
- (b) Free use of "I don't know" is indicated when you don't know.
- (c) Do not hedge, however, on what you do know.
- (d) Make reply quickly.
- (e) Look out for the lawyer's trick of getting the witness to give assent to a slight misquotation of some one of his previous statements.
- (f) Keep your temper.
- (g) Confine your answers to the questions put to you; and point out your rights where categorical answers would be misleading.

F. *Fees for Expert Testimony.* The settling of the amount of the fee is purely a matter of negotiation between physician and lawyer. The attending physician ordinarily makes no extra charge. The following rates conform with ordinary customs:

- (a) For examination of patient \$10 to \$25 is not unreasonable.
- (b) Conferences with lawyer at double the ordinary office call.
- (c) Expert witness ordinarily charges \$25 to \$100 a day for court work.

Two cautions are suitable:

- (a) Don't hesitate to state financial arrangements if questioned in court about them. Anything else than direct frank statements are detrimental.
- (b) The expert witness should send in his bill before the trial, so that he may protect himself against the charge of being financially interested in the outcome of the suit.

G. *Lawful Requirements of Medical Witnesses.*

- (a) No other demand than testimony before the court can be made by any person or agency.

* Report of Lectures on the Medico-Legal Responsibilities of the Physician, given at the Harvard Medical School, Friday, Nov. 19, 1915.

- (b) A doctor's personal notes on a case may be required by the court as evidence, whether or not the doctor is retained by either side. In such a case the physician is legally entitled to no more than a lay witness.
- (c) A physician may be required to testify as an expert without any legal claim for special recompense, but in such event cannot be forced to read up or prepare the case. Therefore more than his offhand opinion on the case as presented to him in court cannot be required.

DR. COURTNEY:

Adherence to the following rules would improve expert medical testimony 100%

- (a) The witness must have accurate and full knowledge of the patient's history as well as present condition. He is not going to be examined in what he does not know unless it be something directly concerning the case.
- (b) An expert who cannot testify in simple terms will find the effect of his testimony soporific only.
- (c) It is not the province of the medical expert to attempt to fix the blame.
- (d) Witness should take his tone from the court. Flippant self-assurance and spurious ease are easily recognized. Attention should be given at all times to the jury, and the voice and temper must be controlled.

MR. A. D. HILL: *Liability of Practitioners.*

The law will not hold liable a well-equipped careful man of reasonable skill, who makes use of such tests and appliances at his command as are reasonable in the particular situation in which he is placed. It is apparent that in the long run the best of men will at some time or other fall below his usual standard. Nevertheless damage suits are based on other grievances than the occasional human failings of physicians.

The main precautions to be taken are:

- (a) Have full records, including explicit statements made to patient in regard to what you could not undertake to accomplish. Incomplete records are the most frequent cause of disaster. Note that charity patients enjoy liability law.
- (b) Exercise greatest care and circumspection.
- (c) Insist on your orders being obeyed; otherwise it is prudent to refuse any responsibility.
- (d) Insurance.

The medical profession should be clearly aware of the temptation in legal procedures to protect fellow practitioners against justice. This temptation is a very subtle one, but it is not hard to see the eventual wrong that professional protection does in lowering the ethics of the medical profession.

MEDICAL MEETING IN THE AMPHITHEATRE OF THE PETER BENT BRIGHAM HOSPITAL, TUESDAY EVENING, NOVEMBER 23, AT 8.15 O'CLOCK.

EXHIBITION OF CASES.

DR. HARVEY CUSHING: A case of Hodgkin's disease showing a very chronic clinical course.

DRS. A. J. HAMILTON AND J. E. ASH: A case of Hodgkin's disease showing an acute clinical course, with pathological specimens.

Paper of Dr. J. L. YATES, of Milwaukee,—

HODGKIN'S DISEASE AND CLOSELY RELATED AFFECTIONS: THEIR TREATMENT BASED ON ETIOLOGY AND MORBID PHYSIOLOGY.

Hodgkin's disease must be classified with the infectious diseases. The microorganism responsible for the pathological processes characteristic of this malady may gain entrance to its host through any chronic lesion, either of the skin or of the mucous membranes.

The investigations carried on by Dr. Bunting in the pathological department of the University of Wisconsin and by Dr. Yates in Milwaukee, have shown that there are three diagnostic criteria for this disease: the histological, the hematological and the bacteriological. As yet the histological studies have shown no fully established pathological entity. The blood picture, however, is very characteristic. It constitutes the most reliable single diagnostic measure, and it forms the best guide for treatment. In following the results of therapeutic measures it is invaluable. All of the animals which were injected with the microorganism isolated by Bunting and Yates showed the characteristic blood pictures. The agent responsible for Hodgkin's disease is a diphtheroid organism ubiquitous in nature. It has been recovered in pure culture from certain of their patients on many different occasions. When the histological and hematological findings have been positive Bunting and Yates have never failed to get pure cultures, except where treatment has previously been instituted. This same diphtheroid organism has been isolated from patients representative of seven different disease pictures. From an etiological standpoint, then, the following diseases must be grouped together. The various pathological changes found here represent different stages of the same disease.

- Group I. Type Hodgkin's.
- Group II. Lymphoma—Large cell
- Group III. Lymphoma—Small cell
- Group IV. Banti's Disease
- Group V. Chronic Hypertrophic Arthritis
- Group VI. Elephantiasis
- Group VII. Mycosis Fungoides

The toxin circulating in the tissues in Hodgkin's disease has a specific action on three types of cells: the lymphoblast, the endothelioid cell, and the fibroblast. The clinical course of this disease, which

shows alternating waves of aggression and regression, may be explained by assuming that the patient is never able to produce sufficient antibodies to overcome the infection.

In the past the patients have always been treated symptomatically. Yates now bases his treatment on an hypothesis which accords with the pathological and clinical aspects of the patients. The portal of entry is first excised. This, in the great majority of cases, is the tonsil. An attempt is then made to throw the balance of power on the side of resistance by excising as much of the diseased tissue as possible, thereby removing the greatest quantity of toxin in the shortest time. To prevent recurrences the wound is thoroughly bathed in iodine, and x-ray treatment is started within a few hours. Later immune serum is administered and proper hygienic measures are instituted. In the treatment the toxin must be neutralized. Unless this be done, whether the glands enlarge or not, the patient is doomed. (Lantern slides were shown to illustrate the cases.)

The presence or absence of periadenitis is of great moment in gauging the therapeutic measures. Great periadenitis points to an unfavorable stage. Excision, accordingly, is not carried out at such a time. To remove an individual gland in Hodgkin's disease for microscopical study should be censured as severely as a similar course in the presence of carcinoma.

Yates and Bunting regard only such patients as cured as have shown no recurrence within five years. In a series of ten cases under observation for from one to eight years: one died from the operation, three succumbed to the disease, four are living and well with excellent chances for cures, and two are absolutely cured—one after six and one after five years.

DISCUSSION.

DR. MALLORY: The diseases mentioned in the first three groups of Drs. Yates and Bunting should be regarded as different expressions of one process—the lymphoblastoma, Hodgkin's disease and the lymphomata, then, are the clinical expressions of a new growth and are not infectious diseases. (Lantern slides were shown to illustrate the reaction of different tissues to the lymphoblastoma.)

DR. WRIGHT: A natural flora of organisms exists in the lymph nodes in smaller or larger numbers. It is conceivable that a tumor might arise from a pleomorphic organism in the nodes. There is still considerable skepticism regarding this, however, since nothing like Hodgkin's disease or lymphoma has been produced by inoculating animals.

DR. WOLBACH: The bacteriologic work done by workers in general on Hodgkin's disease is very poor. The papers published on this disease give no satisfactory account of the characteristics of the organism supposed to be responsible for the pathological changes. It is absolutely essential that the properties of these microorganisms be adequately laid down. In view of the meagre bacteriologic reports at present, and the wide distribution of the diphtheroids in the body, the speaker is skeptical regarding the organisms held responsible for Hodgkin's disease.

DR. GREENOUGH: The most important point from the clinical side is that the mortality from this disease under the usual conditions is close to 100%. Yet Dr. Yates points to a small proportion of his

cases which appear to have been definitely benefited by his measures.

DR. YATES: There is no known type of neoplasm which has constantly a temperature such as is seen in Hodgkin's disease. The tissues from some of Yates' and Bunting's experimental animals show a type of reaction which is very suggestive of the changes found in Hodgkin's disease. A perfectly characteristic blood picture appeared in the animals injected with this organism.

[Book Reviews.

The Medical Record Visiting List or Physicians' Diary for 1916. Newly Revised. New York: William Wood and Company. 1915.

The Physician's Visiting List for 1916. Philadelphia: P. Blakiston's Son and Company. 1915.

The Practitioner's Visiting List for 1916. Philadelphia and New York: Lea and Febiger. 1915.

The approach of a new year brings the annual editions of the standard visiting lists for physicians. These are as convenient as they are necessary, and the possession of one is essential to the practitioner who aims at efficiency and preparedness. Which one he shall select for his own use depends largely on his personal taste and habit, since all are suitable to the purpose for which they are designed.

The Etiology of Typhus Exanthematicus. By HARRY PLOTZ, PETER K. OLITSKY AND GEORGE BAEHR. 1915.

This monograph, reprinted from the *Journal of Infectious Diseases* of July, 1915, represents the original researches of the authors in the pathological laboratory of the Mount Sinai Hospital of New York, as a result of which they were enabled to determine the etiology of exanthematic typhus and to prepare an antitoxic and prophylactic serum therefor. In this important piece of investigation the bacteriologic studies were made by Dr. Plotz and the serologic studies by Dr. Olitsky. The book is illustrated with a number of charts and tables and one full-page colored plate. It closes with a valuable alphabetic bibliography of 136 titles. The volume is of peculiar interest as presenting the primary record of a piece of medical research whose practical value received such prompt contemporary demonstration in the European War.

Guide to the Use of Tuberculin. By ARCHER W. R. COCHRANE AND CUTHBERT A. SPRAWSON. New York: William Wood and Company. 1915.

This book, as the title would indicate, is intended primarily for the general practitioner, and on this the reviewer would base his only criticism. In this country, at least, and doubtless to greater or less extent elsewhere, the general practitioner is in no position, either by training or experience, to undertake the use of tuberculin, particularly in cases of pulmonary tuberculosis, without danger of doing grave harm. The reviewer firmly believes that tuberculin and its administration in the vast majority of cases should be left to those who are trained in its use and who know not only its value, but its dangers and limitations. Aside from this the book is of value as presenting the subject of the therapeutic and diagnostic use of tuberculin in a short, yet clear, form. There are many illustrative charts, and numerous other diagrams and illustrations. Although it may be doubtful if many general practitioners will obtain much information from this source, for students, physicians in sanatoria and others interested in the subject of tuberculin the book will be helpful.

What to Eat and Why. By G. CARROLL SMITH, M.D., Boston. Second edition, thoroughly revised. Philadelphia and London: W. B. Saunders Company. 1915.

The first edition of this book was reviewed in the issue of the JOURNAL for Nov. 2, 1911 (Vol. clxv, p. 696). In this second edition the author has incorporated several accessory chapters, notably one upon exercise and one upon rheumatism. The sections dealing with affections of the stomach have been rewritten and much extended and other chapters have also been enlarged and brought to date. These additions increase the value of the work, which should be considerable to practitioners. The same comment made in our previous review may properly be repeated of this present new edition.

The Development of the Human Body. By J. PLAYFAIR McMURRICH, A.M., Ph.D. LL.D., Professor of Anatomy in the University of Toronto. Fifth edition, revised and enlarged. Philadelphia: P. Blakiston's Son and Company. 1915.

The first edition of this convenient manual of human embryology was published in 1910. That the work should have reached this fifth edition within five years is evidence of the value which it has proved to possess for students and teachers. The increasing interest in embryology dur-

ing this period has led to a rapid advance in its knowledge and several of the chapters in this volume have accordingly been recast and their material expanded. At the close of each chapter is a useful bibliography of reference literature on the subject concerned. The book is admirably illustrated with 287 figures, several of which are printed in colors. In comparison with the larger and more elaborate scientific works on embryology, this volume affords a most practical and serviceable handbook of an abstruse subject.

Notes on Dental Metallurgy. By W. BRUCE HEPBURN, L.D.S., Glasgow. Second edition. New York: William Wood and Company. 1915.

This British manual of metallurgy for the use of dental students and practitioners was first published in 1910. It was intended as a practical guide in preparation for examination and for the manufacture of fillings in practice. Of particular importance are the chapters on the various alloys, solders and amalgams. This second edition aims to bring the subject matter to date, and in it the chapters on alloys and amalgams have been wholly rewritten, the latter by the author, the former by Dr. A. Campion, professor at the Royal Technical College in Glasgow. In this chapter have been added many useful alloys not included in the first edition. The appendix contains a number of useful tables. The work should recommend itself for its technical accuracy and clearness to students, teachers and practitioners.

The Book of the Fly. By G. HURLSTONE HARDY. New York: Rebman Company. 1915.

The discovery of the importance of the house fly as a host and disseminator of various infections led first to the publication of technical and scientific works on the fly, notably such as the volumes by Hewitt reviewed in the issues of the JOURNAL for June 10 (Vol. clxii, p. 867) and for July 8, 1915 (Vol. clxxiii, p. 57). With the diffusion of popular knowledge and interest upon this subject, there arose need for works of a simpler type. The author, in his sub-title, describes the present monograph as a "nature study of the house fly and its kin, the fly plague and the cure." In his preface Dr. Halford Ross comments on the importance of such a work to stimulate and guide intelligently the popular co-operation which is essential to the success of any efforts toward fly extermination. The text of the book is illustrated with a half-dozen figures, the appendix with seven full-page plates, illustrating the anatomy of the fly. The appendix also contains tabular classifications and descriptions of the various fly species and families. The book should be of value, not only to the laity, but to students, teachers and public health officials.

DISTRICT MEDICAL SOCIETIES.

DURING the past few years a feeling which is not without good foundation has arisen in the minds of those interested in the broad problem of preventive medicine that, to a certain degree at least, the medical profession is lagging behind the general public in the interest which it takes and the knowledge which it shows of this most important phase of medicine. As a result of this feeling, last year the National Tuberculosis Association organized a plan whereby it was hoped that state medical societies, and through them the district medical societies throughout the country, would take the necessary steps to ensure at least one meeting a year of their annual programs devoted to the subject of tuberculosis and its prevention. Word to this effect, offering hearty coöperation and help in the way of material and lantern slides, was sent out by the National Association to the sec-

retaries of state and local societies. In Massachusetts, at least, there is every reason to believe that these notices received little or no attention.

In the annual program of what is presumably the largest, most powerful and influential district medical society in this state, for instance, for the past two years and for this ensuing year the subject of tuberculosis and its prevention has not been considered except by casual mention. A well known physician was heard to remark that if one wanted to clear the hall at any medical society meeting, one had only to mention the subject of tuberculosis.

While it is in no way claimed that tuberculosis and its prevention is the most important problem in medicine, it may be truly stated, however, that the tuberculosis problem, the cancer problem, and the venereal disease problem are the greatest questions yet unsolved which confront us today.

It would seem, therefore, that the suggestion sent out by the National Tuberculosis Association that one meeting a year of each district society be devoted to the consideration of this subject in its broadest possible aspects, is a most wise one. It would be of greater advantage if some definite arrangement could be made in this state whereby the chairmen and secretaries of local tuberculosis societies were asked to submit the program for their yearly meetings to some central committee and to arrange these programs so as to include one evening each year devoted to tuberculosis, cancer, venereal disease, and public health, respectively. The difficulties arising in regard to speakers, papers, material, lantern slides, etc., could easily be met by the various societies and other organizations interested in these subjects.

This is an excellent opportunity to coördinate and improve a somewhat chaotic condition of the yearly programs of the average district medical society in Massachusetts. It is to be hoped that the Massachusetts Medical Society will take some step as here suggested to bring this about.

MEDICAL MILITARY REORGANIZATION.

WHILE the subject of military preparedness is attracting national attention, the Southern Medical Association, at its recent meeting in Dallas, Texas, from November 8 to 11, took occasion especially to discuss the subject of medical mili-

tary reorganization, and the importance, in any scheme for enlarging the military provisions of this country, of providing adequately for the medical care of the increased number of troops. As a result of its discussion, the association adopted a series of resolutions, which are published in full in another column of this issue.

The attention of the District Medical Societies throughout the state is called to these resolutions. Fellows of the Society are urged to get into touch with their congressmen and to insist on the importance of incorporating in any bill for an increased army, provision for a sufficient number of trained medical men to care for the health of the soldiers both in time of peace and in war. The experiences of the Spanish War without a definite pre-arranged plan for the medical department of the army are still fresh in mind.

As a matter of fact the measure to be proposed in Congress this winter makes no attempt to provide for sufficient medical attendance in a crisis, or even in times of peace. No class of men is better qualified to determine the necessary number of medical officers than the physicians of the country as represented in the American Medical Association and such more local organizations as the Southern Medical Association. In the present era of preventive medicine, when thorough knowledge of the etiology of disease and of precise methods of caring for the sick and wounded make possible the prevention of epidemics such as used formerly to devastate armies in the field, it is imperative that the health of any army, whether in peace or in war, should be entrusted to especially trained men. Failure to make such provision is only to invite catastrophe and is sure to result in the occurrence of avoidable diseases and in the suffering and loss of wounded from lack of proper treatment. Ultimately, it is the state, as well as the individual, which suffers from the needless sacrifice of human lives through negligence.

As a part of national military preparedness, for peace and for or against war, it is therefore essential that suitable provision for the army and navy medical corps should form an integral part of any legislative program that may be advanced. Congress has already convened and will act shortly. Whatever is to be done in the way of influencing its opinion and action must be done promptly. It is the duty of individual

physicians and of medical organizations throughout the country to urge upon their representatives, individually and collectively, the cardinal importance of the medical aspect of military reorganization.

A NEW DEPARTMENT.

SINCE the reorganization of the JOURNAL at the beginning of the current year, it has been its intention to present more intimately to its readers, material proceeding from the hospitals and laboratories, affiliated with medical education in the community which it represents. To a considerable extent this has been already possible, and it is expected that it will become possible to a steadily increasing extent hereafter.

On another page of the present issue of the JOURNAL is presented for the first time a new department, established in furtherance of this representative design, under the heading of Harvard Medical School. This department will contain reports of societies meeting at the school or its allied hospitals, accounts of work of special interest that may be in progress at any of these institutions, preliminary reports of laboratory or clinical research, and other briefer items of particular interest pertaining to medical education.

In the present issue there appears in this new department the first systematic report of one of the medical meetings at the Peter Bent Brigham Hospital. These meetings are held nearly every week, and it is expected that their proceedings will be regularly chronicled by the secretary. The other item appearing in the new department this week is a summary of one of the Friday afternoon exercises held at the school for the fourth-year class. This series of exercises, which is an innovation this year in the medical curriculum, aims to review for the benefit of the graduating class important topics selected from the entire field of medicine. It is believed that these exercises, conducted by experts, lead to the production of material which will be of value, not only to students, but especially to practitioners of medicine. It is the purpose of the JOURNAL, therefore, to present weekly reports of these exercises prepared under the authority and supervision of the instructor responsible for the exercise in each case.

The JOURNAL calls the attention of its readers to this new department with the hope that it may prove of interest and value to them, not only as friends of medical education, but as practitioners in the larger clinical fields.

MASSACHUSETTS MEDICAL BENEVOLENT SOCIETY.

THE recent annual meeting of the Massachusetts Medical Benevolent Society should recall to the profession the quiet but constant beneficence of this peculiarly characteristic medical charity. For many years the society has annually devoted its entire income to the charitable relief of unfortunate physicians, their widows or children, whom circumstances have made dependent upon the pecuniary aid of others. During the year ended in October, 1915, twenty-three beneficiaries were in this manner saved from acute destitution. Many other deserving cases needed assistance which, for lack of more funds, the society could not give.

It has always been a characteristic point of honor in our profession, as in no other, that its members and their families should freely receive professional service in sickness. It should be felt as equally an honorable duty among physicians to see to it that none of their professional brethren suffer, in old age or adversity, from destitution or physical hardship.

The hardships of war fall with peculiar severity upon our professional colleagues and their families in Europe; but at the same time it should not be forgotten to make provision for the inevitable hardships of misfortune in our own professional community. Every physician to whom the opportunity offers, should feel it a privilege, as well as a pleasure, to assist the Massachusetts Medical Benevolent Society in its work of charity and relief.

A STUDY IN HOSPITAL EFFICIENCY.

DR. E. A. CODMAN has recently issued a report of his work on hospital organization as regards the end-result system. This system, as it was presented before the Clinical Congress of Surgeons of North America at its meeting in Novem-

ber, 1913, is set forth in the Report of the Committee on Standardization of Hospitals. Dr. Codman states the object of his report to be twofold. "In the first place (Part I) to continue the illustration of the use of the end-result system given in the first report; and in the second place (Part II), to show the reasons for believing that the great factor militating against the adoption of the end-result system in our large hospitals is the failure of the trustees to realize the financial value of hospital positions to those holding them." Part I contains reports of 270 cases recorded in the manner approved by Dr. Codman and in accordance with the system he advocates. Part II is a study in hospital efficiency, based on the financial report of a private hospital. It expounds the theory that "a hospital appointment is a big asset to the doctor and especially to the surgeon," in return for which he demonstrates his usefulness to the institution and requites it for the benefit which he derives from it by means of the end-result system. In short, Dr. Codman states clearly and logically and by the use of figures that the results to be gained by such a system are: (1) private institutions guaranteeing good results and subject to litigation if they do not get good results; (2) charitable institutions, in which the patients are true experimental material, but guaranteed the best treatment by the end-result system, which makes it for the interest of each surgeon (selected because of his fitness) to get better results than did those before him.

MEDICAL NOTES.

THE WEEK'S DEATH RATE IN NEW YORK.—According to Dr. William H. Guilfooy, Registrar of the Department of Health, the past week has been one of the healthiest in the history of New York City, especially so far as the prevalence of infectious diseases is concerned, as shown in the number of deaths reported from these causes. There was one death reported from scarlet fever, three from measles and eighteen from diphtheria and croup in the entire city, these figures being much lower than at any previous corresponding week of which we have records. The number of deaths reported from broncho-pneumonia, which is a disease chiefly of childhood, was sixty-seven, as compared with ninety-four during the corresponding week of 1914. The adult population was correspondingly healthy; in other words, at all the age groupings of the population there was a decline in the number of

deaths compared with the corresponding week of 1914. There were two causes of mortality that showed an increase, and those were organic heart disease and pulmonary tuberculosis.

The number of deaths reported in the entire city during the week was 1318, with a death rate of 11.84 per one thousand of the population, as against 1389 deaths and a rate of 12.98 during the corresponding week in 1914, a decrease in the absolute number of deaths of 71 and a decrease in the rate of 1.14. The death rate for the first forty-eight weeks of 1915 was 13.54 per one thousand of the population, as against a rate of 13.71 for the corresponding period in 1914, a decrease of .17 of a point.

TUBERCULOSIS WEEK, DECEMBER 6 TO DECEMBER 12.—The week of December 6 to 12 has been designated as National Tuberculosis Week. During this time, an effort will be made to revive interest in tuberculosis as still the greatest public health problem. This year special emphasis will be laid on the importance of regular medical examinations. Wednesday, December 8, has been designated "Medical Examination Day," and hundreds of thousands of circulars are being distributed to the people of New York City, urging them to consult their family physician, to submit to a thorough physical examination at his hands, and carefully to follow the advice he gives.

The New York Health Department has secured the coöperation of the Tuberculosis Committee of the Charity Organization Society and the Tuberculosis Committee of the Brooklyn Bureau of Charities, and through these agencies is distributing a large number of health leaflets through the churches and the labor unions of this city. The services of the field force of the Metropolitan Life Insurance Company and the Prudential Life Insurance Company have also been placed at the disposal of the Department for the distribution of these leaflets.

The physicians of every city can render invaluable aid to the cause of public health by advocating regular medical examinations to their patients and by carrying out the examinations with care and thoroughness.

REDUCTION IN THE COST OF PRODUCING RADIUM.—It has been announced that the Secretary of the Interior, through the Bureau of Mines and Dr. Howard A. Kelly of Baltimore, has succeeded in reducing the cost of the production of radium. The cost of radium at the Denver Experiment Station, including the first experimental work, was \$37,000 a gram of radium metal. The market price of radium for the last two or three years has been \$120,000 to \$160,000 a gram.

"The Bureau of Mines produced this radium in coöperation with what is known as the National Radium Institute, which was organized for the purpose of studying the curative properties of radium and not for private gain. These

investigations from the first have been under the direction of Dr. C. L. Parsons, of the Bureau of Mines, the funds being furnished under coöperative agreement between the National Radium Institute and the Bureau of Mines by Dr. Howard A. Kelly, of Baltimore, and Dr. James Douglas, of New York. Up to the present time, five grams of radium have been extracted from the carnotite ores, and about half of it has been delivered in finished form to the Kelly Sanatorium, in Baltimore, and to the Memorial Hospital, in New York."

AFFILIATION OF MEDICAL SCHOOLS.—It is announced that on November 15, final plans were arranged for a union between the Medico-Chirurgical College of Philadelphia and the Medical School of the University of Pennsylvania. It is expected that this affiliation may also be joined by the Polyclinic Hospital of Philadelphia, which maintains a graduate medical course for physicians.

MANUFACTURE OF DE-ALCOHOLIZED WINE.—In the issue of the JOURNAL for August 19, we commented editorially on the possible use of de-alcoholized beverages as a preventive of inebriety. In a recent issue of the *Scientific American* is quoted from *L'Italia Agricola* a description of the manufacture of such de-alcoholized wine as a new feature in the Italian wine industry. The product contains all the components of wine including the ethers, aldehydes and tannic acid to which the taste is due. In Italy the process of this manufacture is by fractional distillation under relatively low pressure whereby the alcohol alone is removed.

FIRST CRUISE OF THE ANDROSCOGGIN.—The United States Coast Guard Cutter *Androscoggin*, which has again been assigned this season for hospital duty off the fishing banks, returned to Boston on November 24, from her first cruise off the Nova Scotia coast, during which relief was given to the crews of several fishing vessels.

EXHIBIT ON HISTORY OF SURGERY.—In connection with the Congress of Clinical Surgeons, meeting in Washington, November 26-27, an interesting exhibit of books and pictures, illustrating the history of surgery, has been prepared by Dr. Arnold C. Klebs, at the invitation of Colonel C. C. McCulloch, Librarian of the Surgeon-General's Office, and may now be seen in the Library Hall of the Army Medical Museum. Dr. Klebs is at present unofficially attached to the Surgeon-General's Library in an advisory capacity.

FOOT AND MOUTH DISEASE.—Report from Washington states that by a federal order issued on November 27, the quarantine against foot and mouth disease was completely raised in Massachusetts and New Jersey and modified in a number of counties in Illinois.

PREVALENCE OF MENINGITIS, PELLAGRA, POLIOMYELITIS, SMALLPOX, AND TYPHOID FEVER.—The weekly report of the United States Public Health Service for November 19, 1915, states that during the week ended October 30, there were 23 deaths from cerebrospinal meningitis in Sacramento, Calif.; 31 cases of pellagra in Nashville, Tenn.; 4 of poliomyelitis in Cleveland, Ohio, and in New York City; 9 of smallpox in New Orleans, La.; and 81 cases and 8 deaths of typhoid fever in New York City.

EUROPEAN WAR NOTES.

CHOLERA IN AUSTRIA-HUNGARY AND GERMANY.—During the week ended August 22, 287 cases and 166 deaths of Asiatic cholera were reported in Hungary, and during the week ended August 29, 212 cases and 124 deaths. During the week ended September 18, there were six cases and one death of cholera in Germany. Nearly all the cases were among civilians. During the same period the disease was prevalent among prisoners of war in detention camps at Erfurt, Magdeburg, Marienwerder, Oppeln, Posen and Stettin.

In Galicia from December 27, 1914, to September 18, 1915, the official statistics in the monthly *Bulletin* of the International Office show 27,591 cases of cholera and 15,270 deaths. Of these, 699 cases with 180 deaths occurred among prisoners of war, and only 172 cases with 34 deaths among soldiers. Judging from the statistics for Austria for the period from August 15 to September 18, it would appear that the epidemic has been more severe among the civil population, as there were no fewer than 15,175 reported cases and 9,113 deaths, of which only 327 cases with 32 deaths occurred among the troops, and 39 cases with 12 deaths among prisoners of war.

WINNER OF A NOBEL PRIZE.—In a recent issue of the *JOURNAL* we noted the award of the Nobel Prize in medicine to Dr. Robert Bárány of Vienna. Dr. Bárány is a Hungarian born in 1876 and has devoted his life chiefly to work upon the ear. At the outbreak of the European War, being then a lecturer at the University of Vienna, Dr. Bárány volunteered in the medical service and was assigned to have charge of a military hospital of 250 beds at Przemyśl. Upon the capture of this city by the Russians he was made prisoner and transported to a camp at Irkutsk in Siberia. Here he fell ill with malaria and was later transported to Nerw. Dr. Bárány's work has been chiefly in the diagnosis and treatment of diseases of the internal ear, especially with regard to the interpretation of aural vertigo. Garrison, in his history of medicine for 1914, says:

"Labyrinthine vertigo or vestibular nystagmus, is interpreted by Bárány as a disturbance of function of the vestibular nerve, or the organs to which it is distributed, and he has traced its origin to a large number of different causes with which it might be confused. He has intro-

duced a number of ingenious differential tests, such as production of nystagmus by irrigation of the external meatus with cold or warm water, or by having a patient try to point at an object with his eyes shut after having previously touched it, and he has been able to prove his case by successful operations on the cerebellum, or the internal ear. He has also devised a "noise" machine for testing paracusis Willisii, and other diagnostic novelties."

WAR RELIEF FUNDS.—On Dec. 4 the totals of the principal New England relief funds for the European War reached the following amounts:

Red Cross Fund	\$142,764.01
American Ambulance	70,799.58
Serbian Fund	54,018.76
Allied Fund	42,680.30
French Fund	26,824.01
Armenian Fund	22,488.53
Surgical Dressings Fund	13,097.50
LaFayette Fund	12,833.99
Italian Fund	12,311.69

BOSTON AND NEW ENGLAND.

THE WEEK'S DEATH RATE IN BOSTON.—During the week ending December 4 there were 243 deaths reported, with a rate of 17.41 per 1000 population, as compared with 219 and a rate of 15.86 for the corresponding week of last year.

There were 31 deaths under 1 year, as compared with 33 last year, and 90 deaths over 60 years of age, against 64 last year.

Total deaths reported in 48 weeks from Jan. 2 to Dec. 4 were 10,864, against 10,864 for the corresponding period in 1914.

Deaths under 1 year reported in the same period were 1843 against 1837 for the corresponding period in 1914.

During the week the number of cases of principal reportable diseases were: Diphtheria, 54; scarlet fever, 41; typhoid fever, 2; measles, 43; whooping cough, 61; and pulmonary tuberculosis, 52.

Included in the above were the following cases of non-residents: Diphtheria, 7; scarlet fever, 3; measles, 1; and tuberculosis, 4.

Total deaths from these diseases were: Diphtheria, 4; typhoid fever, 2; measles, 1; whooping cough, 1; and tuberculosis, 24, in which are included the following deaths of non-residents: Diphtheria, 1; measles, 1; and tuberculosis, 2.

ALUMNI OF THE UNIVERSITY OF MARYLAND SCHOOL OF MEDICINE.—The regular winter meeting of the New England Alumni of the University of Maryland School of Medicine was held at the Quincy House, Boston, Wednesday evening, December 8, 1915. The following papers were read: "The Duty of the General Practitioner to the Hospital, and the Duty of the Hospital to the General Practitioner," by Dr. Louis A. Russlow, Randolph, Vermont; and "Thyroids in General Medicine," by Dr. Frank Matulaitais, Boston, Mass.

INSANE AND FEEBLE-MINDED IN MASSACHUSETTS.—It has been computed that the number of feeble-minded in the State of Massachusetts is increasing at the rate of 139 persons per year. The average annual increase of the insane during the last twenty-five years has been 378. The insane, feeble-minded, epileptics, voluntary patients in insane hospitals, inebriates and those requiring temporary care amount to 17,204, or one for every 208 of the population.

So far as the birthplaces of the insane can be determined, 54% were born in the United States and 45% in foreign countries. But of the parents of the insane, 31.72% of the mothers were born in this country, and 68% abroad. Of the fathers, 30% were born in this country and 69% in another country.

As regards sex, the female insane outnumber the male—7263 to 6859. In the case of the feeble-minded the situation is reversed, the males numbering 1363 and the females 1068.

PAYING WARD AT THE MASSACHUSETTS GENERAL HOSPITAL.—Final arrangements have been completed for the erection of the new paying ward at the Massachusetts General Hospital. The addition will be eight stories high, built of limestone and brick, and will be one hundred and fifty feet long and fifty feet wide. The first floor will be devoted to administrative purposes. The operating room and etherizing room will be on the top floor. The remaining six floors will provide accommodation for about one hundred patients. The rooms are large and sunny, and will be made as homelike as possible. Those on the front of the building will have fireplaces. That this new ward will fill a long-felt want both on the part of physician and of patient by providing facilities for expensive medical care to those of moderate means and by affording members of the staff convenient means to care properly for such patients, there can be no doubt.

RADIUM TREATMENT AT CARNEY HOSPITAL.—It is announced that a gift of 25 milligrams of radium has been made to the Carney Hospital by M. Douglas Flattery, a Boston attorney, for the purpose of establishing a clinic for the treatment of malignant diseases. Mr. Flattery's gift to the Harvard Medical School for the establishment of a fellowship for the study of cancerous and allied growths was recently noted in the *JOURNAL*.

SIAS LABORATORY AND BROOKS HOSPITAL.—The Sias Laboratory and the Brooks Hospital, institutions erected by Mrs. Charles D. Sias in memory of her husband, are completed and were opened in Boston Nov. 18. The laboratory is intended to be used for original research, and its use, without charge, to any medical graduate who wishes opportunity to do such work. The superintendent of the hospital is Miss Elizabeth Peden, a graduate of the Massachusetts General Hospital.

Massachusetts Medical Society.

COPY OF RESOLUTIONS PASSED BY
THE SOUTHERN MEDICAL ASSOCIATION, AT
DALLAS, TEX., NOV. 8-11, 1915.

THE attention of the District Medical Societies is called to the following resolutions which have been transmitted to the President of the Massachusetts Medical Society by the President of the American Medical Association:

Whereas, The President and the Honorable Secretary of War have announced in the public press that a scheme for the reorganization of the Army will be presented to Congress at its coming session, which will materially increase the military establishment, and

Whereas, We recall the indignant protests and criticisms of the Nation at the failure to provide adequately for the sick and wounded at the beginning of the Civil War and the Spanish-American War, and

Whereas, It is known that this failure was due to the lack of a sufficient number of medical officers in the regular army and a means for increasing the medical establishment at the outbreak of war, and

Whereas, In spite of the lessons of the Spanish-American War, which were fresh in mind in the reorganization of the Army in 1901, the Medical Department was not properly increased, and no provision was made for its expansion in time of emergency, and

Whereas, to correct the defects in the 1901 legislation, subsequent legislation was necessary in which the medical profession of the United States was called on to assist;

Therefore, Be it resolved by the Southern Medical Association, in session at Dallas, Texas, that the Secretary of War be petitioned to make adequate provision in the reorganization of the Army about to be presented to Congress for a sufficient number of medical officers for the regular establishment, which provision should aggregate a proportion of medical officers of, at least, seventy-five hundredths of one per cent. of the enlisted strength of the Army, or such numbers as the Surgeon-General of the Army may deem necessary, and,

Be it further resolved that the Secretary be petitioned to make provision in this reorganization for the expansion of the Medical Department at the beginning of war, by calling into service in the Medical Reserve Corps physicians from civil life who have been instructed in their special duties as medical officers in our summer camps, and otherwise as the War Department may see fit.

Obituary.

FREDERICK WILLIAM RUSSELL, M.D.

DR. FREDERICK WILLIAM RUSSELL, for many years a practitioner in the town of Winchendon, Mass., died at the residence of his son-in-law, Dr. Frank J. Hall, 4119 Cedar Springs Avenue, Dallas, Texas, November 20, aged 71.

He graduated from Harvard College in the class of 1869, and from the Medical Department of New York University in the class of 1871. He was a hospital steward during the Civil War, and served in that capacity under his father, Dr. Ira Russell, who was commissioned by Abraham Lincoln to organize the hospital service in Tennessee, Missouri, and Arkansas, both father and son being in service at the close of the war at Prairie Grove, Ark.

After his graduation in medicine he associated himself in practice with his father in Winchendon, where father and son together conducted "The Highlands," a private institution for the treatment of mental and nervous invalids, an institution established many years ago by Dr. Ira Russell, and one of the first of its kind at that time.

After the death of his father, in 1888, Dr. F. W. Russell continued "The Highlands" up to three years ago, when from ill health, he gave up active work to make his home (together with his wife, Mrs. Caroline Marvin Russell, who survives him), with his daughter, Mrs. Frank J. Hall, in Dallas. During his brief residence in Dallas, because of his genial nature and interest in all social and scientific bodies, he made many friends.

Having been for many years a member of the Worcester County (Mass.) and various other medical societies of New England, he was elected honorary member of the Dallas Medical and Surgical Association, and was elected President of the Texas Harvard Club, which honor he declined, but was elected and re-elected honorary president of this organization.

In connection with his medical studies, Dr. Russell made a lifetime study of entomology, and became an entomologist of note. He was a member of the American Entomological Society, and during his life, made a rare collection of moths, and wrote some valuable manuscripts and classified and made valuable plates of various specimens of moths of his collection.

His remains were taken by his son, Walter M. Russell, of Emporia, Kansas, to Winchendon, Mass., where they were laid to rest in the family lot.

BENJAMIN JOY JEFFRIES, M.D.

DR. BENJAMIN JOY JEFFRIES was born in Boston, March 26, 1833. He died November 21, 1915, in his 83rd year. He descended from a long line of distinguished ancestry, in whom he took great pride, the first of whom to come to this country from England was David (1658—1742), who graduated at Harvard in 1708. His father and grandfather were physicians of Boston. It was his grandfather, John, Surgeon-General of the British forces in America, who crossed the English Channel in a balloon from England to France in 1785.

Dr. Benjamin Joy Jeffries graduated from the Boston Latin School, and received his degree of A.B. in 1854, and three years later, that of M.D., from Harvard, after which he continued his medical studies in Vienna, principally under Prof. Arldt and Prof. Hebra, for it was his intention on returning to Boston to practise in the two specialties, dermatology and ophthalmology, and for two years he gave especial attention to these two classes of affections. In connection with Dr. Francis P. Sprague and the writer, he opened a free dispensary for their treatment in Eliot street. He also began with his colleague the translation of Hebra's great treatise on dermatology. He also gave a course of lectures on this subject to the medical class and wrote a small work on "Diseases of the Skin." Gradually he gave up his dermatological practice and devoted himself exclusively to the study and treatment of diseases of the eye.

He held the post of ophthalmic surgeon to the Massachusetts Charitable Eye and Ear Infirmary from 1866 to 1902, a devoted service. He was a member of many local, national and international ophthalmological societies and congresses. He was especially interested in the subject of color blindness, and his treatise, "Color Blindness, its Dangers and Detection," published in 1879, was long the standard authority on the subject and led to important public measures for the safety of railroad transportation and travel on the sea. He published also a book entitled "The Eye in Health and Disease." He was particularly interested in the question of the proper administration of ether in ophthalmic surgery and made a special trip to England to demonstrate the better methods in use in America to his foreign colleagues.

Dr. Jeffries was very fond of the ocean and yachting, and spent many summers at Swampscott and on the shores of Hingham Harbor, and latterly, at Marblehead.

He was greatly endeared to many of the surviving members of the profession and to his classmates, now reduced to seven in number. In the last few years he had undertaken the duties of class secretary.

He wrote many papers read at medical so-

cieties, the principal titles of which are given in the appended footnote.*

He was a member of many medical and scientific societies and a constant attendant at their meetings. He was long an officer of the Boston Society of Natural History. He was surgeon of the Boston Independent Corps of Cadets, and took a strong interest in military matters. He belonged to several social clubs; the Porellian and Hasty Pudding while in college; the Thursday Evening and Somerset later in life. He was much interested in local colonial history in which his ancestry for several generations had played a conspicuous part.

He married in 1872 Marian, daughter of Charles Shimmis. There were two children from this union, Charles who died during his freshman year in college, and a daughter, Marian, recently married to Dr. James Howard Means, Harvard, 1907. Dr. Jeffries' wife died in 1888, since when he had lived in the old family mansion, 15 Chestnut street, with his daughter who has taken the most devoted care of him in his declining years. Dr. Jeffries remained in fairly good health and continued to practice his profession until the last three or four years. His strength and functions have slowly failed, and he died of quick pneumonia on November 21, an honorable, genial man.

STEREOPTICON LOAN LIBRARY.

THE United States Public Health Service has recently issued the following information regarding the stereopticon loan library which it maintains in Washington:

"The stereopticon loan library established by the United States Public Health Service, consists of over 2000 views, the majority of which are original, dealing with the aspects of various public health problems. Additions are constantly being made to the collection. The slides are classified by diseases or subjects, the following being the respective divisions of the library:

Alaska. Eighty-three views depicting living conditions in the territory of Alaska, the type of villages, and the diseases from which the natives suffer.

Children and Children's Diseases. The various eruptive diseases of children are shown in 50 views. Chiefly of interest to physicians.

Health Exhibits. Over 90 photographic slides of the exhibit of the U. S. Public Health Service at the Panama-Pacific International Exposition. Many of these views explain the means of dissemination of different diseases, the mortality therefrom and the value of preventive measures. All are original.

Hookworm. The geographic distribution of the disease, its economic importance, the life history of the parasite, its invasion of human tissue and the resulting effects, are demonstrated in a series of over 90 slides.

Indians. Housing and living conditions among American Indians. Shown in 50 views.

Leprosy. Forty-five slides depicting the disease. Principally of service to physicians.

Living Conditions. Contains a relatively small number of slides. See other subjects.

Malaria. Prevalence of the disease, the malarial parasites, larval, pupal and adult developmental stages of mosquitoes, breeding places, methods of extermination, including oiling, drainage and the types of fish destructive to larvae. Prevention of the disease by screening and the use of quinine. 275 views.

Milk. Eighty views showing tuberculous cows, proper and improper stabling, care and treatment of dairy herds, methods of obtaining

pure milk, spread of milk-borne epidemics, and the value of sanitary measures.

Miscellaneous Subjects. Sewage disposal, fumigation and cleaning of railway cars, and views relating to Rocky Mountain Spotted Fever.

Mouth Hygiene. Twelve slides showing the development of the teeth.

Parasites and Organisms. Over 200 views of the common organisms causing the diseases of man, including different types of water organisms. Also the developmental stages of fleas, lice, flies, and disease-bearing vermin.

Pellagra. Statistical data, geographical distribution and the lesions of the disease presented by 60 photographic slides.

Plague. Perhaps the most complete collection of original plague slides extant. Practically every aspect of plague prevention is demonstrated, including the eradication of rodents and squirrels, methods of rat-proofing, ship fumigation, the examination and classification of rats, the plague organism, and the relation of fleas to the spread of the disease. Over 500 views.

Rural Schools. Not yet complete. Ten slides.

Service General. The activities of the U. S. Public Health Service, depicted in 320 views. Quarantine vessels and stations, methods of fumigation, the examination of passengers, detention barracks and quarantine procedure. The mental and physical examination of immigrants, types of immigrants, and immigration stations. Marine Hospitals, including the tuberculosis sanatorium at Fort Stanton, New Mexico.

Smallpox. Ninety slides illustrating the eruptive stages of the disease, the protection afforded by vaccination and the lesions thereof.

Trachoma. The disease in its acute and chronic stages, and such effects as pannus, entropion and blindness. Trachoma among the American Indians and the relief work of the Public Health Service in the mountains of Kentucky are also shown. One hundred and twenty slides, many of which are colored.

Tropical Diseases. Incomplete. Filariae, trypanosomes, and intestinal parasites illustrated, together with the common infections of the tropics. Forty views.

Tuberculosis. One hundred slides showing the economic loss from tuberculosis, susceptible races, the tubercle bacillus, pathological conditions in the lungs, the relation of the disease to improper housing and the causes predisposing to infection. Also the methods of care, precautions to be exercised and the benefits of sanatorium treatment.

Typhoid Fever. Of great public health interest. The rôle of uncleanness, infected milk, polluted water, improper sewage disposal, and flies, in the dissemination of the infection. Methods of prevention, including proper care of milk supplies, avoidance of water pollution, and the prevention of fly breeding; 350 views.

Yellow Fever. Mosquitoes in different stages of development, preventive measures, including

detention camps. The discoverers of the means of transmission of the disease.

HOW TO USE THE STEREOPTICON LOAN LIBRARY.

The slides are loaned to physicians, health organizations, educators, welfare workers, and others, without cost. Persons desiring slides should advise the Bureau as to what subjects they are interested in, so that the proper catalogues may be forwarded. The slides should be selected by number, and the request made upon the application blank. If desired, the Public Health Service will undertake to make the selection, provided the applicant will state what he wishes to illustrate. There is no arbitrary limit within which the slides are to be returned, but as the demand far exceeds the supply, it is expected that they will be returned at the earliest possible moment. Stereopticon lanterns are not loaned, but as the slides are of standard size, $3\frac{1}{4}$ by 4 inches, any lantern may be used. It is expected that slides broken by careless handling or packing will be replaced; these to be ordered from the Government contractor by the U. S. Public Health Service, and the bill therefor to be paid by the borrower.

It is requested that in returning the slides, a letter of transmittal be forwarded, stating the approximate number of persons to whom the views have been shown. The container should be labelled with the name and address of the sender, and returned by express prepaid or by mail. Photographs, from which it is possible to obtain slides of public health interest, will be gladly received and promptly returned."

RABIES AND DOG MUZZLING IN NEW YORK.

In the weekly bulletin of the New York Department of Health for November 20, appears in part the following statement about rabies and the muzzling of dogs in that State.

"The presence of rabies in New York City either in men or animals is a reflection on the work of the Department of Health, but it is a more severe reflection on the loyalty and co-operation of the citizens of the city as indicated by an opposition to a most necessary and justifiable ordinance, viz: the muzzling of dogs when at large.

Rabies has existed both in men and animals for a long period of years, but of late has been assuming proportions likely to occasion well grounded alarm in the minds of all who appreciate what this means. Previous to 1904, rabies was rarely present in this city, only an occasional case being encountered. One case was found in 1904, none in 1905 and only three in 1906. Since 1906, cases have been encountered each year, lately in somewhat increasing numbers. The disease has not been confined to dogs and other animals, but has taken toll in human life as well.

In both human beings and animals, rabies is almost invariably fatal. In a large percentage of cases of human beings bitten by rabid animals, prompt use of the anti-rabic treatment has been most effectual in preventing the development of rabies. This treatment is administered free of charge at the Pasteur clinics of the Department of Health, or the material will be furnished to private physicians for administration.

Although most willing to furnish treatment for rabies, the Department of Health cannot overlook the fact that this disease is entirely preventable. With proper appreciation of the significance of this truth and cheerful coöperation on the part of persons owning dogs, rabies could be speedily and effectively controlled and in time be prevented.

In England, rabies was very prevalent until effectual muzzling of dogs and a strict dog quarantine demonstrated that the disease could be controlled. Since 1902, there has been no rabies in all England. The chart of Frothingham clearly demonstrates the effectiveness of this measure: when it was loosely enforced, rabies increased; but when rigidly enforced, the disease soon diminished and then disappeared.

The Board of Health of the City of New York has declared* that dogs, unmuzzled and at large, are a nuisance, dangerous to life and detrimental to health. This declaration was broad and comprehensive and forbade owners and others to allow dogs at large. For a time, the regulation was rigidly enforced and had a marked effect upon the situation, as can be seen by the experience in the Borough of Richmond. After two years of active work, rabies in this borough was controlled. Subsequently, owing to the influence of agencies hostile to work of this character, this activity was discontinued and rabies soon reappeared.

The dog muzzling law now in force in the city of New York is contained in Section 17 of the Sanitary Code. This reads, as follows:

'No unmuzzled dog shall be permitted, at any time, to be on any public highway or in any public park or place in the city of New York.'

A dog, properly muzzled, is not a menace to the community. For this reason, therefore, and in justice to all other dogs, no dog should be permitted to go at large at any time without an efficient muzzle. According to Webster, muzzling is defined, as follows: To bind the muzzle of, to fasten the mouth of, *so as to prevent biting or eating*.

Some owners claim that certain dogs cannot be efficiently muzzled. This is absolutely not true. Other owners say that a muzzle makes their dogs irritable and surly. Horse owners know that a bridle will do the same to a colt until it is trained. New false teeth do not usually fit comfortably until time and nature soon have made the necessary adjustment, yet

after a time, they are worn without the least discomfort.

So far as dog-bites and rabies are concerned, the ordinary work of the Department of Health is limited to the investigation of reported attacks, the destruction of the biting dog if vicious, and the administration of Pasteur anti-rabic treatment to those bitten by a rabid or suspected rabid animal."

STERILIZATION OF DENTAL INSTRUMENTS.

THE possibility of the transmission of disease through the medium of dental instruments has probably been considered by every occupant of the dentist's chair. It constitutes one of the fears with which a patient is possessed the moment he adjusts himself for his period of treatment. Authoritative instances of the conveyance of contagion in this manner are extremely rare, its frequency not being determinable, although few will deny the possibilities of occurrences of this character.

The list of organisms which may contaminate dental instruments is formidable, but this does not mean that the diseases of which they are the causative factors necessarily ensue if they are accidentally carried into the mouth. Their presence upon dental instruments is, however, an indication of what the surgeons call poor technic. In surgery, poor technic is usually attended with disastrous results, but in dentistry errors of this character may produce no ill effects. In spite of this relative freedom from danger, dentists are determined that their methods shall equal the highest standards.

Cleanliness should be the primary consideration in all dental operations. The white coat of the operator represents more than comfort; it is the symbol of neatness. The dentist who works with unclean instruments, who provides soiled linen, or who places a common drinking glass before his patient, should be judged accordingly. Fortunately the members of the profession who do these things are criticized and suffer from loss of patronage, so that there is a strong tendency on the part of dentists to maintain their surroundings above reproach. With the sterilization of instruments some carelessness may manifest itself, partly owing to the fact that many instruments are injured by such processes, are too complicated to be treated in this manner, or that the public is not competent to detect errors of technic. However, the public is rapidly learning the value of aseptic methods and the proper equipment is now found in nearly all dental offices.

Thorough studies of the sterilization process have recently been made for dentists by the United States Public Health Service, at the request of various dental associations throughout

* Resolution adopted June 17, 1908.

the country, and in a recent publication of that Service detailed information will be found as to the accepted methods for the sterilization of all dental instruments.

Correspondence.

A WOMAN QUACK OF OLDEN TIMES.

BOSTON, MASS., Nov. 26, 1915.

Mr. Editor: Human credulity in high place is well shown in the account given by Bolton of the notorious Mrs. Joanna Stephens, a woman practitioner of medicine, who flourished exceedingly in London about 1738. Certainly from the accounts of the doings of this unscrupulous dame, Perkins of "Metallic Tractor" fame, was a feeble amateur. Proclaiming that she had discovered a remedy of wonderful value in a painful disease, she soon had a large and lucrative practice in the highest social circles in London.

After receiving many enormous fees, she proposed to make the formula of her wonderful medicine public property, for the sum of five thousand pounds. Her friends and enthusiastic patients started a subscription, to collect this amount, but it was not found possible to raise the required sum. Nothing daunted the woman's friends petitioned Parliament, and the petition was granted. A certificate was signed, Bolton tells us, by twenty justices. The certificate bore evidence to the "Utility, Efficacy, and Dissolving Power of the Medicines."

Analysis of these wonderful medicines, three in number, "a powder, a decoction, and pills," showed that the powder was composed of calcined egg shells and snails, the decoction of a mixture of herbs, soap and honey, boiled in water. The pills were made of "calcined wild carrot, burdock seeds, ashens keys, hips and haws, all burned to blackness, soap and honey."

A comparison of the sums spent by the public at the present day for nostrums equally as valueless as the above, is not exactly a compliment to these supposedly enlightened times.

Very truly yours,

WM. PEARCE COUES, M.D.

31 Massachusetts Avenue.

AN IMPERFORATE ANUS.

BOSTON, MASS., Nov. 26, 1915.

Mr. Editor: The case of the child recently born in a western city with distressing deformities, a case which has received altogether too much publicity, brings to mind the following incident:

Many years ago a man brought his son, 14 years old, to the Boston City Hospital for an examination. The boy was operated on soon after birth for an imperforate anus and was dependent upon a pad and diaper. Having no other control over the artificial anus, he was a nuisance to himself and to his family. The father was so disgusted at his son's condition that he proposed to bring a suit for malpractice against the physician who performed the operation. In other words, he proposed to sue the doctor for saving the child's life. His main object in applying at the hospital was to secure experts who would testify for him in court.

The man was assured most emphatically that the physician had done his duty faithfully and skillfully and that there were no grounds whatever for his taking legal action. As he could obtain no experts, no suit was ever brought, so far as known to the writer.

GEORGE W. GAY, M.D.

CHANGES IN THE MEDICAL CORPS, U. S. NAVY, FOR THE FIVE WEEKS ENDING NOV. 27, 1915.

October 26, Surgeon E. B. Williams, detached Norfolk Hospital, to Marine Brigade, Haiti.

P. A. Surgeon G. A. Riger, detached, Texas to Marine Brigade, Haiti.

P. A. Surgeon D. G. Allen, detached, New Hampshire to Marine Brigade, Haiti.

P. A. Surgeon E. U. Reed, detached, N. Y. Recruiting to Marine Brigade, Haiti.

Asst. Surgeon R. A. Torrence, detached, Portsmouth Hospital, to Marine Brigade, Haiti.

Asst. Surgeon A. E. Beddoe, detached, Tennessee to Marine Brigade, Haiti.

Asst. Surgeon E. M. Waterhouse, detached, Montana, to Marine Brigade, Haiti.

Asst. Surgeon C. E. Dragoo, detached, Nebraska to Salem.

October 25, P. A. Surgeon G. W. O. Bunker, to New York Hospital.

P. A. Surgeon A. H. Dodge, from Salem to Portsmouth Hospital.

November 2, P. A. Surgeon A. E. Lee, to Training Station, San Francisco.

P. A. Surgeon A. L. Clifton, from N. Y. Hospital to Melville.

Asst. Surgeon W. G. Espach, from New York to Nashville.

November 3, Medical Inspector R. P. Crandall, to New York Supply Depot.

November 4, P. A. Surgeon R. W. McDowell, from Ozark to Fulton.

Asst. Surgeon F. J. Riordan, from Tonapan to Ozark.

Asst. Surgeon R. L. Crawford, from Nashville to United States.

November 8, P. A. Surgeon F. H. Brooks, from Marine Barracks to Norfolk Yard.

Asst. Surgeon F. H. Haigler, from Dixie to Texas.

November 10, Surgeon F. A. Asserson, to Newport Hospital.

P. A. Surgeon R. A. Warner, from Newport Hospital to New York.

November 13, Surgeon F. G. Abekon, commissioned from June 13, 1914.

Surgeon A. Stuart, to Recruiting Station, Lowell, Mass.

P. A. Surgeon S. L. Higgins, to Las Animas Hospital.

Asst. Surgeon F. H. Bowman, from Delaware to Marine Brigade, Haiti.

November 16, L. W. Spratling, detached, Fleet Surgeon to Norfolk Yard.

Surgeon H. O. Shiffert, from Norfolk Yard to New York.

Surgeon J. F. Leys, from New York December 1, 1915, to Fleet Surgeon, Atlantic Fleet.

November 19, P. A. Surgeon B. F. Jones, from Disciplinary Barracks, Port Royal, S. C., to Marine Barracks, Port Royal, S. C.

P. A. Surgeon H. E. Jenkins, from Disciplinary Barracks, to Port Royal Marine Barracks, S. C.

Asst. Surgeon H. Priest, from Marine Brigade, Haiti, to Norfolk Hospital for treatment.

Asst. Surgeon F. Coros, from Marine Brigade, Haiti, to Norfolk Hospital for treatment.

November 24, P. A. Surgeon D. C. Walton, from Yorktown to Asiatic Station, via Army Transport of January 5, 1916.

Asst. Surgeon A. N. Ross, from Maryland to Yorktown.

NOTICES.

THE AMERICAN SOCIETY FOR THE STUDY OF ALCOHOL AND OTHER NARCOTICS will hold its 45th annual meeting in the parlors of the Hotel Raleigh, Washington, D. C., Dec. 15 and 16, 1915.

This was the first society of medical men in the

world to take up the scientific study of alcohol and other narcotics. Its papers and transactions have been published in the *Journal of Inebriety*, and comprise the first scientific literature on the subject.

Thirty-two papers on different phases of the subject will be read at this meeting by specialists and distinguished medical and scientific men. These studies will be confined exclusively to the facts and conclusions from laboratory and clinical experience.

The public are cordially invited to be present. Programs can be had by addressing the Secretary,

DR. T. D. CROTHERS,
Hartford, Conn.

INFANTS' HOSPITAL, BOSTON.—A clinical meeting of the staff of the Infants' Hospital will be held at the Rotch Memorial building, 55 Van Dyke Street, Friday, December 17, 1915, at 8.15 P.M.

SUBJECTS.

- I. Intravenous Injections in Infants.
 - II. Diagnosis of Duodenal Catheter.
 - III. Demonstration of Cases.
- Members of the medical profession are cordially invited.

HARVARD UNIVERSITY AND MASSACHUSETTS INSTITUTE OF TECHNOLOGY.

SCHOOL FOR HEALTH OFFICERS.

Special Lectures in December.

All lectures will be given from five to six o'clock on the date specified and in the amphitheatre of Building E., Harvard Medical School, unless otherwise specified. All lectures will begin promptly on the hour.

December 7. "Posture and Deformities" (3 lectures). Dr. Robert W. Lovett, Professor of Orthopedic Surgery, Harvard Medical School.

December 10. "Medical Inspection of Immigrants" (2 lectures). Dr. M. V. Safford, Medical Inspector of Immigrants, U. S. Public Health Service.

December 13. "Legal Medicine" (4 lectures). Dr. George B. Magrath, Medical Examiner, Suffolk County.

December 14. "Posture and Deformities." Dr. Lovett.

December 15. "Legal Medicine." Dr. Magrath.

December 16. "Medical Inspection of Immigrants." Dr. Safford.

December 17. "Legal Medicine." Dr. Magrath.

December 20. "Legal Medicine." Dr. Magrath.

December 21. "Posture and Deformities." Dr. Lovett.

Lectures for January, February and March will be announced at a later date.

* Dr. Lovett's lectures will be given at the Children's Hospital, Longwood Avenue, Boston.

UNITED STATES NAVY MEDICAL CORPS.

The next examination for appointment in the Medical Corps of the Navy will be held on or about February 23, 1916, at Washington, D. C.; Boston, Mass.; New York, N. Y.; Philadelphia, Pa.; Norfolk, Va.; Charleston, S. C.; Great Lakes (Chicago), Ill.; Mare Island, Cal.; and Puget Sound, Wash.

Applicants must be citizens of the United States and must submit satisfactory evidence of preliminary education and medical education.

The first stage of the examination is for appointment as assistant surgeon in the Medical Reserve Corps, and embraces the following subjects: (a) anatomy, (b) physiology, (c) materia medica and therapeutics, (d) general medicine, (e) general surgery, (f) obstetrics.

The successful candidate then attends the course of instruction at the Naval Medical School, which will begin on or about October 1, 1916. During this course he receives a salary of \$2000 per annum with allowances for quarters, heat and light, and at the end of the course, if he successfully passes an examination in the subjects taught in the school, he is commissioned an assistant surgeon in the Navy to fill a vacancy.

Full information with regard to the physical and professional examinations, with instructions how to submit formal application, may be obtained by addressing the Surgeon General of the Navy, Navy Department, Washington, D. C.

W. C. BRAISTED,
Surgeon General, U. S. Navy.

SOCIETY NOTICES.

NEW ENGLAND PEDIATRIC SOCIETY.—The thirty-ninth meeting of the New England Pediatric Society will be held in the Boston Medical Library, Friday, Dec. 10, 1915, at 8.15 P.M.

- I. Report of Council and nomination of officers.
- II. Report of Treasurer.
- III. The following papers will be read:
 1. Simple Incision in the Treatment of Pyloric Stenosis, by James S. Stone, M.D., Boston.
 2. Spasmodic: Report of Ten Cases.—Etiology and Treatment, by Fred P. Webster, M.D., Portland, Me.
 3. Fermentative Diarrhea in Infants, by Lewis W. Hill, M.D., Boston.
- IV. Election of officers.

Light refreshments will be served after the meeting.

F. M. BUCKINGHAM, M.D., *President*.
RICHARD M. SMITH, M.D., *Secretary*.

SUFFOLK DISTRICT MEDICAL SOCIETY.—SURGICAL SECTION.—Meeting Wednesday, December 15, at 8 P.M., at the Boston Medical Library.

Address by Dr. William L. Rodman of Philadelphia, President of the American Medical Association, on "Surgery of Gastric and Duodenal Ulcer."

The discussion will be conducted by Dr. George W. W. Brewster, Dr. Franklin W. White, Dr. George W. Holmes, of Boston.

CHARLES L. SCUDDER, M.D., *Chairman*,
W. J. MIXTER, M.D., *Secretary*.

MIDDLESEX SOUTH DISTRICT MEDICAL SOCIETY.—A special meeting of the Society will be held at the Boston Medical Library on Wednesday, Dec. 15, 1915, at 12 o'clock, noon.

Paper:

Dr. William W. Walecott of the State Department of Health will speak upon the following subject:

"Field Work of the State Department of Health on Communicable Diseases."

Dr. Eugene R. Kelley, Director of Division of Communicable Diseases, State Department of Health, will open the discussion.

Lunch will be served at 1.15 P.M.

LYMAN S. HARGOOD, M.D., *Secretary*,
6 Garden St., Cambridge, Mass.

APPOINTMENTS.

CREIGHTON MEDICAL COLLEGE, OMAHA.—Dr. Robert Retzer of the University of Chicago has been appointed professor of anatomy at the Creighton Medical College; and Dr. G. W. Earle has been appointed instructor in pathology and director of the clinical laboratory.

DISINFECTION OF SEPTIC JOINTS.*

By FREDERIC J. COTTON, M.D., F.A.C.S., BOSTON.

INFECTED joints have always been a reproach to our art; their treatment the counsel of despair.

A suppurating joint, infected from without or from within, has been counted among the lost, and not only joints, but lives—many lives—have been lost as well. Nothing could be worse than the story of joint drainage. Today the opening and drainage of joints should be listed not as an operation but as a crime. It is our duty today either to determine and declare a joint infection hopeless, and then to *lay the joint wide-open (not drain it)*, or else to bend all our efforts to an *optimistic attempt to save the joint*; not only to get it healed, but to preserve its function as well.

Years ago, about ten years, I was engaged in opening and washing-out gonococcus joints, as were many others. During the course of this work I learned as a purely empiric matter that such gonococcus joints, whether in the small minority showing positive culture, or the many that gave no viable cultures, that these joints did better if sewed up tightly, than if left to drain through loose suturing; while wick or tube drainage proved, as all have since recog-

nized, no less than disastrous to future function.

Not long after this series had crystallized in my mind the desirability of efficient disinfection and closure in these cases, there came to my hand some cases of really *septic joints* (for the gonococcus is but a facultative pus organism after all), joints with staphylococci particularly, and a few streptococcus joints. These I treated in the same way, sewing the capsule tight, and gradually evolved a definite technic: opening of the joint; irrigation for fifteen minutes (by the watch) with a full stream of 1-15000 corrosive sublimate†; a flushing-out of the excess with salt solution; then a water-tight closure of the capsule by mattress and single sutures in such a way as to leave the synovial membrane cut edge to cut edge, as accurately as may be. Usually the membrane is so swollen as to make this really possible.

The external wound is left wide open or nearly so, for it must be conceded that real disinfection of the external soft tissues is not practicable. After operation there may or may not be an effusion into the joint; if an effusion comes it goes again within one to three days, and is not accompanied by temperature or by any considerable discomfort.

I have not in these cases, with two or three exceptions, resorted to traction for the separation of joint surfaces. There has seemed to be no pain-factor constituting a clinical demand for such treatment, and I see no theoretical reason for it, for these joints show little or no spasm.

† As a rule the best way is to distend the joint; then let it collapse and empty; then distend again. Accurate reaching of all parts of the joint by a direct stream is almost impossible.

* Read before the Hennepin County Medical Society, June 7, 1915, at Minneapolis.

There have been about two dozen such cases treated by this technic, excluding the gonococcus cases, not less than fifteen of them representing infections by staphylo- or streptococci; the majority staphylococcus infections. In looking up the cases for this paper, I have been rather appalled by my inability to find well remembered cases in the hospital records of years ago; cases of failure as well as successes.

There have been two failures: one a punctured wound of the knee in a male adult; treated according to this technic but with a recurrence of the streptococcus infection; laid wide open; patella laid back on thigh; later (after vaccine treatment) subjected to a cleaning-out of granulations from nearly intact cartilage and suture of divided ligaments, regaining in the end a good leg with 45 to 50 degrees of motion. The second case was a knee with an epiphyseal staphylococcal infection in a boy of three; cleaned out and sutured; later the joint broke down and an ankylosis resulted.

The rest have all done well; I cannot give nearly all, and will rest my case on six instances, covering seven pus joints disinfected and sewed up successfully.

CASE 1. Barbara S., aged 10; seen in consultation with Dr. John MacDonnell of South Boston. History of having hurt her knee in jumping down into a cellar and having a few days thereafter noticed tenderness and lameness gradually increasing. The fall was about two weeks previous. She had been in bed a week when seen, with great pain and steady fever. Physical examination showed a sturdy young Polish girl; nothing of note save the right knee, which showed great distention of the joint, tenderness and limitation of motion, with local heat, but without redness. I sent her into the City Hospital for immediate operation, as a septic joint, of the osteomyelitic type; one of the juxta-epiphyseal infections.

The same day, Jan. 16, 1909, I operated under ether. The joint was opened on the inner side and found full of thick, creamy pus. Usual irrigation with H_2O_2 , followed by salt, and the joint closed in the usual way. Then through an incision on the outer side, a large popliteal abscess was opened and drained. The cultures taken from both joint and abscess were reported as staphylococcus pyogenes aureus by Dr. Mallory.

The temperature at entrance was 102.5 degrees, but three days later reached 99 and ran along about that level for some time. At eight days there was no fluid in the joint; tenderness was less; wound over joint nearly closed. Deep sutures held; there was no joint leakage. Two weeks after the operation, the joint was all right, but there was more pus from the popliteal space. This continued. An x-ray taken showed a sequestrum and it was decided to remove it.

March 15, 1909, under ether, I removed a sequestrum $2 \times 2\frac{1}{2} \times 3\frac{1}{4}$ inches from the femur, exactly at the back, starting at the epiphyseal line and running up. The temperature went up the next day and then down permanently.

March 28, 1909. Still draining from sinus behind;

joint wound healed; knee joint motion of 60 degrees. Discharged to the out-patient department.

About a year later, I removed a little bone chip with forceps; function of the knee had been perfectly good before that. After this chip came away, the sinus promptly closed.

I sent for this girl and examined her a year ago; five years after the operation. She has grown big and strong, and save for the shin scars, the two knees cannot be told apart; an absolute restoration, anatomically and functionally. She can sit on the heel of this leg.

This case was exhibited before the Clinical Surgical Congress October 28, 1915.

CASE 2. Pat. F.; seen in consultation with Dr. Thomas F. Carroll of Brockton; then of Norwood, Mass., Aug. 7, 1912. The patient, a man of 40, had an old scar and had had a childhood osteomyelitis, leaving some lameness and an old scar on the inner side of the thigh. The story was that he had then been some seven weeks ill; bedridden and feverish; that the knee had been opened by some doctor. Owing to his extreme deafness, detail data were scanty. There was, as Dr. Carroll had recognized, an infection of the joint as well as a recurrence of the old osteomyelitic trouble. The joint was full. The man's general condition was very poor indeed; an anemic factory worker to begin with, dragged down by seven weeks' of sepsis. Subnormal temperature at the time.

I got him into town, and into the City Hospital, and operated the next morning, under ether, with a three-inch long incision of the outer side of the knee. There was a large amount of thinish pus in the joint, under much pressure. There was no change in the joint surfaces, beyond slight purple tinting and minimal swelling of the synovial membrane. The joint was irrigated in the regular way; 15 minutes of corrosive; then salt. It was then carefully sutured—the capsule with No. 1 chromic gut and the skin with silkworm gut,—then, on account of the presence of pus all about the wound, a sealed dressing was put over it. Then an incision on the inner side of the femur opened up the expected pocket in the condyle, which was cleaned of debris and packed. The wound into the joint leaked some serum, but never any pus, even from the skin wound. There was never any synovial leakage. This wound was protected from outside infection by intermittent sealing until it closed solidly Aug. 23. Cultures taken at operation showed staphylococcus pyogenes albus, both in the pus from the joint and in that from the bone. September 9 under ether, a sequestrum was removed from the internal condyle about $1 \times 1\frac{1}{2} \times 1\frac{1}{2}$ inches. October 10, 1912, he went home with a small bone sinus but with free joint motion.

Later reports from Dr. Carroll were of a persistent small bone sinus but never any recurrence of joint symptoms or of effusion in the joint. He never regained full motion, but got serviceable motion; as good motion as he had had before the knee joint infection.

CASE 3. Antoinette De L., aged 6; admitted to the City Hospital June 12, 1914, under Dr. David Scannell, for a septic elbow wound, ten days old. This appeared to clean up and June 22 she went to the out-patient department for dressings. On July 10, 1914, 28 days after the injury, she was readmitted and came to my service. The left elbow was tender and swollen with a granulating wound and

sinus, the sinus obviously going into the joint. There was motion of 30 degrees and there was little or no spasm. (It is remarkable how little spasm there is to a septic joint in comparison to a T. B. joint, for instance, owing, I think, to the fact that in sepsis, the process is in the synovial lining, not primarily in the articular ends of the bone). An x-ray showed haziness about the lower end of the humerus; no focal lesion.

July 12, 1914, operation under ether. Oblique incision cutting the triceps tendon; very little thin pus in the joint. Joint surface of humerus showed some loss of cartilage; cartilage of radius and ulna intact. Synovial membrane red, spongy and in spots ragged. Usual irrigation preceded by carbolic 95% to the raw humeral surface; excess cleared, as usual, with alcohol. Then the corrosive and then salt solution and closure of the capsule and suture of the triceps tendon. Then carbolic and alcohol to the outer wound and only two or three loose sutures in the skin. Cultures showed mixed infection with staphylococcus predominating.

July 20 (eight days) deep wound entirely solid; only serum from outer wound. July 24, wounds all healed; 45 degrees of joint motion. Discharged to the out-patient department for exercises. Seen two months later at which time there were very definite adhesions and motion was pretty much gone; child in excellent condition.

In this case the patient came to operation after there was real damage to the synovial joint surfaces, too late to prevent adhesion, but the joint disinfection and the aseptic closure of the joint worked perfectly well, despite the unfavorable conditions.

CASE 4. Lloyd S., aged 9. After a slight trauma, developed a knee-joint effusion with temperature. The joint was tapped and clear fluid obtained; a second tapping showed pus. About a week after the first effusion appeared, the joint was opened on either side and drains introduced. Nine days after this, he came into my hands, the drains still in situ. He had just come on a stretcher from middle Pennsylvania to Boston, and was not in the best of shape, though a healthy boy.

On Aug. 29, 1914, I operated under ether; laid the joint open on either side, excising the granulating wounds, in which the gauze drains lay; washed out as usual with 1-15000 corrosive, and then with salt solution, and sewed up the capsule tight, leaving the outer wound almost wide open.

The temperature fell directly and though a little suppuration developed after five days, near the upper end of the quadriceps pouch, it yielded to camphorphenol dressings promptly.

Restoration of motion to 45 degrees was prompt and painless. Here we met a check and on Nov. 28, 1914, under primary anesthesia, some adhesions were ruptured. From then on restoration of motion was rapid until 90 degrees was reached. Now motion is almost perfect; function as good as new.

In this case, owing to the long duration of infection, there was some loosening of ligamentous capsule, and an apparatus was worn for a time to counteract the tendency to backward subluxation of the tibia. There is now nothing left of this. This patient was shown to the Clinical Surgical Society last fall.

There is some question whether this infection was from within or without. There was, I understand, a bitter local difference in Pennsyl-

FIG. 1. CASE 4.
Taken at his home in the fall of 1914, and sent to me.

vania owing to the allegation that the first man's trocar had infected the joint. Cultures at the first opening are said to have been mixed staphylococcus and streptococci. When the case came to me, cultures showed straight staphylococcus pyogenes aureus. I believe it to have been a case of hematogenous infection starting near the epiphysis, as in our first case, though in this case, no sequestrum developed. The important point in this case, like the last, is that the joint was an open infected joint, and in this case had been open for nine days with drains in the joint, yet real disinfection was possible.

In February, 1915, Dr. E. H. Place, in charge of our "South Department" infectious hospital, having heard of some of the cases, asked me to see a case there. He told me that, in all the years of his experience there, the South Department had never saved a septic joint, to say nothing of the mortality in these cases, and in convalescence from diphtheria and scarlet fever, such septic joints are not very unusual.

The case to be seen was a post-diphtheritic suppuration of the elbow.

CASE 5. The patient, Isaac G., 8 years old, was admitted for diphtheria Jan. 17, 1915. The infection had attacked the larynx as well as the fauces and tonsils. He was promptly intubed. So far as the K. L. infection went, he did fairly well, but on Feb. 8, 1915, had developed multiple arthralgia with a distinct septic type of temperature.

Feb. 10: temperature remained up; of septic type; fluctuation evident in left wrist; right elbow and right ankle; much pain.

Feb. 11th: I saw him and operated immediately under ether.

The wrist and ankle infections were merely peri-articular abscesses. The right elbow joint was, however, full of thick pus. It was opened on the outer side and irrigated and sewed up, according to my technic, the external wound being left entirely open. The culture was reported as pure staphylococcus aureus.

Feb. 16: The note says—"elbow healing up rapidly; no discharge; no limitation of motion; no discharge from right ankle; temperature gradually approaching normal."

FIG. 2. CASE 4.
Further pictures of Case 4. Taken at the same time as Fig. 1.

Feb. 18: Left hip swollen and tender; temperature slightly elevated.

Feb. 20: Operation on left hip. In this joint the capsule was already "blown-out" and gone. The joint was washed and drained but not handled ac-

cording to my technic; it could not be!

Mar. 7: Periarticular infection at the ankle opened up.

Mar. 20: Elbow wound healed; motion perfectly free.

FIG. 3. CASE 5.
On the left flexion of the disinfected right arm; on the right full extension taken about ten weeks after operation.

Apr. 23: Discharged to my ward in the main hospital. At this time the elbow joint was perfectly normal. The infected hip healed and did well but has nothing to do with the especial technic under discussion.

The photographs show the result in the elbow joint.

This was a pyemic joint in a child who was in wretched condition after a long siege of severe diphtheria. The result speaks for itself.

CASE 6. The second case at the South Department was Charles F., a boy of seven years, who entered the hospital Mar. 17, 1915, then being six days ill. He had a rather severe scarlet fever; typical. For ten days nothing happened; then after lysis his temperature came to normal.

Mar. 28: He had paracentesis performed on right ear.

Apr. 5: Left drum punctured.

Apr. 6: Right mastoid infection showed itself.

Apr. 7: Operation on right mastoid.

Apr. 16: Pain complained of in left elbow joint; some swelling and fluctuation; exquisite pain on motion.

Apr. 19: Left elbow joint opened under ether; about three ozs. of thick yellow pus were obtained. Joint dealt with in the usual way, washed and sewed up. Culture showed streptococcus pyogenes.

Apr. 21: Joint showed no signs of infection, though the temperature still remained up. At this time a bronchopneumonia appeared.

Apr. 22: Pain in the right knee; much tenderness to pressure or on motion; swelling and fluctuation.

Apr. 24: Pain on dorsum of right foot.

Apr. 26: Operation on left foot (a periarticular abscess) and on the right knee. From the knee about 5 c.c. of blood-stained pus was obtained; rather thin. The joint was washed and closed in the usual way. Cultures later showed a mixture of staphylo- and streptococci. At the same time an extra-auricular hip abscess was opened. The next day the temperature was normal.

May 2: The left elbow showed a perfectly mobile joint, with the external wound clean, if not aseptic. The right knee showed some recurrence of effusion and a good deal of tenderness to touch, but the process seemed to be essentially extra-articular.

May 11: Pulmonary consolidation appeared; temperature 101; pulse 130 to 170.

May 12: He died.

Autopsy showed not only pneumonia, but a basal meningitis. Both joints were clean; the elbow was as good as new in every way; it was not opened. The knee showed a bit of periarticular infiltration and an ounce or two of effusion; was opened up; fluid clear and proved sterile. Specimens taken from the joint showed no bacteria in the tissues by any of the various stains. The synovial membrane showed a little fibrin at the surface; a little inflammatory reaction; a trifling infiltration with leucocytes; that was all that we could find. Dr. F. B. Mallory kindly went over the slides with me, and expressed it as his estimate of the intensity of the process that it was about what you would expect after an irrigation with corrosive or other moderate irritant.

Here is a case, most unfavorable in every way, unable to handle his finally fatal general infection, yet, despite the feebleness of resistance, two serio-

ously-infected joints were *disinfected* one after another and remained clean. One returned absolutely to normal condition; the other stayed sterile and was nearly normal before his death from meningitis. Unfavorable as the result was, as to survival, no more conclusive test of the efficiency of this method of joint disinfection should be asked for.

Just what happens after disinfection I do not profess to know clearly; the procedure has been one of gradual empiric growth, based purely on the clinical findings. Whether the corrosive used remains behind in sufficient quantity to impair the growth of bacteria, or whether the synovial infections we have so long dreaded are, after all, only *surface* joint infections, at first, is hard to say. I am inclined to the latter view, but dare not omit the corrosive.

Those of us whose lot it has been to watch the horrid progress of drained joints, know that it is not the pus in the joint so much as the pus steadily draining from the joint reservoir into the soft tissues of the thigh, behind and above the knee, for example, that kills. We shall all, I think, incline to the hypothesis that the joint itself is more tolerant to sepsis than the books give it credit for; to believe that surface disinfection plus natural resistance may be the answer. However this may be, the fact seems established that this technic suffices for an efficient sterilization of joints infected not only by the facultative pus organisms, but also by the frankly pyogenic bacteria.

In the milder cases (as in the gonococcus joints) the advantage of an open washing is mainly in the removal of debris that contributes to later adhesions; in the septic cases it seems that actual removal of infection is accomplished.

There is one very definite limitation to this method. I have not yet worked out any scheme for using this scheme in infection of the closed joints, hip, shoulder, ankle, etc.; joints that are non-distensible by pus or irrigation fluid. Given such a joint, the capsule is already gone before we reach the case. Disinfection may be tried, but closure of the joint is not practicable. Such successes as I have had in the treatment of such cases by disinfection with camphophenol dressings have no bearing on the matter in hand.

In such cases there is much to be said for Murphy's formalin glycerin injections, if the process can be diagnosed before capsule rupture; later I can see little chance even for this method. In the distensible joints, on the other hand,—the knee with its quadriceps pouch, the elbow with its subticipital joint space, pus can collect in considerable amount, enough to be obvious, long before there is tension enough to threaten the integrity of the capsule.

In these cases, I believe the technic here presented to be the procedure of choice. All septic products present, fibrin as well as pus, are removed. The efficiency of disinfection is, I think, pretty well shown. The results are not pretty good only, but nearly always perfect.

THE BACTERIN TREATMENT OF CERTAIN CHRONIC PYOGENIC DERMATOSES.

BY CHARLES C. DENNIE, M.D., KANSAS CITY, Mo.,

AND

JOHN H. BUFFORD, M.D., BOSTON.

[From the Skin Department of the Massachusetts General Hospital.]

THE attention of the writers was attracted by the number of cases of chronic pyogenic dermatoses in the Skin Clinic of the Massachusetts General Hospital, in which, it seemed to them the results were unjustifiably poor. Investigation developed the fact that the "failures," almost without exception, had been treated solely by external methods of various kinds for considerable periods of time. It was rarely that a case was found in which bacterin therapy had been used. It seemed to them that the opportunity to determine the comparative value of bacterin treatment and the prevailing external procedures, could not be passed by. This series of experiments was the result.

The following conditions were adopted for the conducting of the work:—

All cases must be chronic, that is, the duration of the disease must be three months or over. In two or three patients the history was less than three months, but they presented very extensive lesions.

The cases should be selected from the failures of previous methods. Some few had not been treated at all when they were admitted to the clinic, but the lesions were of such character that it was thought best to institute bacterin treatment at once. All external treatment was forbidden. Under the stress of unusual conditions a few exceptions were made to this rule, which are duly recorded below. Internal disturbances were to be corrected as far as possible, and every effort made to put the patient in the best physical condition.

Strict rules were to be given for the hygienic care of the person; unsanitary conditions remedied when possible; the bodily functions regulated and the diet revised and prescribed.

Seventy cases were selected for the experiment, in whom occurred the following diseases: acne vulgaris, 35 cases; furunculosis, 21 cases; folliculitis, 14 cases. In order to give the investigators a still broader scope by comparing the relative efficiency of autogenous and stock bacterins, the seventy cases were roughly divided into two groups, one of which was to receive only autogenous and the other stock preparations. In both instances, however, the bacterins employed were made by the writers themselves. No commercial products were used. When the autogenous bacterins were made, a large amount was prepared and the excess used as the stock preparations.

The actual method of making the bacterins was as follows: The contents of the lesion was planted upon glucose agar slants and incubated at 37.5°C. for the succeeding twenty-four hours. The growth was then examined to determine its vigor and purity. (If more than one kind of bacteria was discovered, the various colonies were counted and the relative number of the respective colonies determined, sub-cultures were then planted, and from these a bacterin was made which retained the same relative number of organisms.) If a vigorous growth was obtained, it was macerated with a platinum loop, mixed thoroughly with a one-third of one per cent. carbolic normal saline solution, which was added until a certain opalescence was secured and allowed to stand for fifteen minutes. The supernatant fluid was pipetted off into a sterile container and the organisms counted by both Wright's method and the counting chamber. To this concentrated mixture, saline solution, containing one-third of one per cent. pure carbolic acid to the e.e., was added until the resultant mixture contained approximately a half billion organisms to the cubic centimeter. The suspension was heated for twenty minutes at 56°C. and allowed to stand at room temperature for four days. During this time it was planted three times upon agar slants, and if no growths were found it was ready for use.

It was our practice to give an initial dose of not less than one hundred million and not over four hundred million killed organisms. The last injection was often two billion. The total number of doses rarely exceeded ten and the interval between was from four to ten days.

The administration of bacterins was governed by the local reaction at the point of injection, such as redness, heat, slight edema, and tenderness upon pressure which appeared within four to twelve hours after administration and sometimes remained as long as forty-eight hours. If this reaction did not occur either at the first or any of the subsequent injections, a new preparation was made and administered. The ineffectiveness of the first bacterin was in all probability due to the fact that the right organism was not recovered or that the preparation had been injured in the process of manufacture.

The general reaction was usually so slight that it escaped the attention of the patient. When there was an increase in the intensity or number of eruptive elements, the following dose was much smaller and was given when the untoward symptoms had subsided. If the patient improved up to a certain point and then remained at a standstill, a new bacterin was prepared and administered for the following reasons: first, the old preparation might have lost its potency, or, second, the organism might have built up an immunity to their own toxins.

If the patient grew progressively worse after each injection of bacterin this mode of treatment was discontinued as it was found to be very difficult to raise the patient's resistance to the

specific organism again. In two cases of sycooses this phenomenon was observed.

General Treatment. All patients who belonged to the acne group were closely questioned concerning their hygienic surroundings, their mode of living and their attention to the bodily functions. It was found that the great majority disregarded the most simple rules of skin hygiene, such as frequency of bathing, gentle removal of comedoes, etc. Many of them ate their meals at irregular hours and did not select their food with the proper care. All of them either volunteered the information that they were constipated or admitted it when questioned.

The acne patients were instructed to rub the lather of a non-irritating soap (castile or any standard soap which does not contain an excess of alkali) in the affected parts and to follow this immediately with cloths wrung out of hot water. After this procedure the comedoes were very easily removed with a suitable instrument. This was followed by the application of hot and cold cloths used alternately for five minutes. Lesions containing pus were to be opened immediately with a sterile needle. All patients were encouraged to remain in the open air as much as possible.

Diet for Acne Patients. Each person was placed on a coarse vegetable diet, to which he was rigidly held during the whole course of the treatment. In order to reduce dietetic errors to a minimum, the patient was instructed to carry a small note-book in which he jotted down each article that he ate at every meal and any article that he wished included in his diet. This book was inspected at the end of each week, and all undesirable things were forbidden for future ingestion. The central idea in this diet was to secure a large bulk with a comparatively small amount of nutrition, and yet so balanced that

the total caloric value would not be less than that demanded by the human organism. Milk, eggs, fat meats, butter, potatoes, bananas, pastries, soups and all highly seasoned or concentrated foods were prohibited.

The breakfast consisted of fruit, wheat bran with an equal part of dry breakfast food and cream, graham toast and honey, and coffee with cream. For luncheon the following was given: cold meat (roast beef, veal, mutton or fowl), two coarse vegetables (beets, carrots, turnips, parsnips, sweet potatoes, cabbage, green beans or peas, sweet corn, egg plant, radishes, tomatoes, lettuce, etc.), and stewed fruit. The dinner consisted of meat (beefsteak, lamb chop, fish or fowl), two coarse vegetables, fruit salad, coffee or tea. Graham bread was eaten at all meals. The purpose of the diet was twofold, first to correct the constipation and second to prevent over-eating; both results were secured in a most gratifying manner.

Tabulation of Cases. It was thought best to tabulate the series. The cases were divided into:—

Acne.

1. Furuncular type,—large deep-seated lesions containing much pus and somewhat resembling furuncles.

2. Deep indurated type,—large pea size lesions containing some pus and a larger amount of caseous material.

3. Comedo type,—small shallow lesions containing a central comedo embedded in pus.

Furunculosis.

Ordinary boils occurring on various parts of the body.

Folliculitis Staphylogens. (*Sycosis Vulgaris.*)

Pyogenic involvement of the hair follicles in the bearded region. In one case the pubic region was involved also.

An examination of the tables gives, in a concise form, the following facts:—

Sixty-four per cent. of all cases treated by bacterins were apparently cured, twenty per cent. were benefited and sixteen per cent. received no benefit whatever.

Autogenous bacterins were superior to stock, excepting in the treatment of furunculosis, where no difference could be seen.

In most cases a permanent cure resulted from the use of bacterins. This contention is supported by the fact that there were only two recurrences in those who reported at the end of one year.

In acne the best results were obtained in the indurated type. The comedo type responded less favorably and the furuncular type least favorably.

Of the three pyogenic dermatoses, the best results were secured in furunculosis.

The action of bacterins in the treatment of sycosis was very erratic; in one case of twenty years' duration where external treatment had been faithfully used for five years and where stock bacterins had been administered, autogenous bacterins were used with remarkable success. On the other hand two cases were very much aggravated by this form of treatment.

The average number of doses administered in successful cases was, eight in acne, four in furunculosis, and four in sycoses.

In nearly all cases the initial dose was two hundred million, and the final, one to two billion, killed organisms.

The most favorable interval between doses was found to be five days in acne, four days in furunculosis and seven days in sycoses.

Pure cultures of the staphylococcus albus were found in all the cases of indurated and comedo type of acne and in seven of the fourteen cases of folliculitis. Mixed cultures of the staphylococcus albus and aureus were found in six of the seven cases of furuncular acne and in three of the twenty-one cases of furunculosis, and in two of the seven cases of folliculitis. Pure cultures of the staphylococcus aureus were found in eighteen of the twenty-one cases of furunculosis. One case of folliculitis showed a mixture of staphylococcus albus and streptococcus pyogenes. Mixed cultures were grown from the lesions of sixteen per cent. of the patients in this series. This clearly demonstrates the fact that the offending organisms should be determined by culture before a patient is given stock bacterins. It would be better to say that because of this fact autogenous bacterins should always be given when possible.

In furunculosis and in the successful cases of folliculitis staphylogenes, bacterins are in all probability directly responsible for the cure of the patient; but this assertion cannot be proven to be true in the treatment of acne. It is not the purport of this paper to establish that claim. The main object in all bacterin therapy is an attempt to raise the resistance of the individual to the specific organism which is responsible for the pyogenic formation. When pus is no longer present in the acne lesions the result of bacterin treatment has been secured; but this treatment cannot correct those faults which underlie the formation of these lesions, and for that reason the general treatment, as already described, was instituted, and to this due credit is given for the part it played in the treatment of acne.

In conclusion we wish to thank Drs. C. J. White, Harvey and Towle for the privilege of studying these cases and for their valuable suggestions in the preparation of the manuscript.

ALOPECIA SYPHILITICA.*

By DOUGLASS W. MONTGOMERY, M.D.,
SAN FRANCISCO.

THE baldness of syphilis is not always a definitely characteristic symptom, but it is a very important one when typical, and may be the only one to attract attention. This is particularly true as regards observation by the patient, with whom anything relating to a fall of hair is usually a matter for anxiety, and with whom also the other slight symptoms of a mild syphilis in the secondary stage may escape notice, for the alopecia of syphilis occurs only in the secondary stage of the disease. On the part of the physician also a knowledge of the peculiarities of this form of alopecia may lead to a search for other luetic symptoms, and so clear up an otherwise puzzling condition.

As before remarked, luetic baldness is not always definitely characteristic. It may be a simple defluvium such as occurs in all the fevers, or it may be almost complete of a very considerable area of the scalp, simulating alopecia areata. Syphilis, however, does sometimes cause a baldness that is so typical as to be almost pathognomonic of the disease. It consists of thinned out, irregular, indefinitely bordered places about the size of the end of a lead pencil or less, making the hair look as if it had been cut by running the point of a scissors up into it. If the hand is swept up the back of the head, bending back the hairs, a vast number of little bald spots will be brought into view. The French call these patches *clairières*, which is delightfully descriptive when one reflects that a *clairière* signifies an open or cleared space in a forest, where all the trees are not necessarily gone, but are thinned out. These cleared areas are most numerous over the sides and back of the head, exactly in the situations where in a man they are most observable, so that even if they escape the patient's own observation they rarely do that of his neighbors, who may be relied upon with neighborly friendliness to call them to his attention.

When the ordinary baldness of advancing years is beginning and the scalp can be seen faintly at the back of the head in the neighborhood of the whorl, it is said that "the moonshine is breaking through"; carrying out the same comparison in the present affection, instead of one, fairly large, centrally located area, there are numerous thinned out, light patches, comparable to the "starlight" appearing through the clouds.

Besides the characteristic alopecia of the scalp, there may be a less characteristic one of the eyebrows. In such cases the hairs fall from the outer third of the brows, or there may be a patchy alopecia dividing the brow into two or three parts. This is called "*la signe de l'omni-*

* Read before the Pan-American Medical Congress, San Francisco, Cal., June 18, 1915.

bus," the sign of the omnibus, because if one sits opposite to the person, as in an omnibus, a snap diagnosis may be made. Such "snap" judgments, however, are not to be encouraged, and if such an irregularity of the brows is noticed, it is better to employ it rather as a hint to look for further symptoms than as one on which to base a diagnosis. In the street cars one can easily observe what a vast number of brows there are that depart from the assumed normal graceful curve. There are those that are naturally almost eyebrowless, and there are others that have a bushy black bar passing straight across above the nose, so that if there were many such the term glabella would never have been invented. Between these two extremes there are all sorts of irregularities.

FIG. 1.

Alopecia syphilitica in a young man suffering from early constitutional syphilis. The patches are very small and the baldness is temporary.

As an instance of the importance of this apparently trivial symptom take the case of a young man who called for advice last September for a patchy thinning out of the hair, principally over the back of the head, and a generalized thinning out of the eyebrows. He complained of nothing else whatever, and would not have called excepting for the remarkable appearance his trouble gave him. And there was nothing more remarkable about his alopecia than just that there were thinned out spots scattered quite thickly over the back and sides of his head, with no alteration whatever in the scalp as regards an eruption, or increase of dandruff, or itchiness. And yet the condition was typical, and could not be due to anything else than syphilis.

A search for luetic symptoms revealed a fading roseola, with a generalized adenopathy, with the largest nodule in the left groin, indicating the location of the primary sore in some situation where the lymphatics emptied into the groin glands. On the inner surface of the prepuce there was a hyperemic edematous patch centered by a cicatrix. He then admitted having contracted gonorrhea four months before, and said that there appeared about a month afterwards a "Narbe," or cicatrix in the above-mentioned spot. A month after this, that is, about two months before coming to me, he was confined in a hospital under a physician's care for two weeks on account of a dropsy in the legs. Although he then had the alopecia, neither it nor any of the other luetic symptoms had attracted notice, and the cause of the dropsy in the legs had not been ascertained.

The history of this dropsy rendered a careful examination of the urine necessary as it might have been due to nephritis, an occasional accident in the course of secondary syphilis. Nothing was found indicative of this, however. A treatment with salvarsan and injections of grey oil was promptly instituted, with a consequent rapid disappearance of all the syphilitic symptoms, including the characteristic alopecia.

Another interesting point was that shortly, without any treatment at all, the syphilitic symptoms in this man would have completely vanished, leaving him absolutely unaware of the nature of his infirmity. Even the growth of hair would have undergone restitution, because the alopecia of syphilis never gives rise to permanent baldness.

Another still more interesting point in these cases of mild secondary syphilis is that they are more apt to be followed by grave visceral syphilis and lesions of the nervous system, such as tabes, than the severer ones. The opinion that this is so is gaining ground, and is attributed by some to a difference in strain in the invading spirochete. These grave consequences may be due, not to a difference in the micro-organism, but to the lack of vigorous treatment, or even to the entire absence of treatment, as nearly happened in the instance above mentioned.

In another case the problem was a different one, and shows what an infinite variety there may be in even such a simple symptom. A negro applied for advice on account of falling of hair that he had noticed for the past month. He showed the characteristic, scattered, patchy thinning out, and a search was instituted for other symptoms.

He had had an eruption on the face five or six months previously that had evidently been papular, as he used to cut it on shaving. Later an eruption appeared scattered over the body as scaly papules, which only itched on changing his clothes at night. About two months before coming to me he had feverishness at night with profuse sweating that had lasted for about two

weeks. During the time the eruption was out he was under the care of a man who was accustomed to treat syphilis, but who evidently had not made a diagnosis of lues. Such a slip is, however, not to be too severely criticized, as physicians in this city are, as a rule, unaccustomed to seeing syphilides in negroes, in whom the cutaneous rashes differ decidedly in their appearance from those seen in whites. Furthermore the papulo-squamous eruption that this man probably then had, is one that is notoriously deceptive. However this may be, when he applied to me for treatment there was no eruption present either on the mucous membranes or skin, but he had many darkly pigmented spots, evidently the remains of a previous eruption, on the forehead, shoulders, lower part of the back, arms and legs. Those on the forehead were the most significant, as being possibly the result of a corona veneris, and the popular syphilide had probably extended back across the scalp and was presumably the immediate cause of the areolar fall of hair. This was just the kind of case in which a Wassermann test was desirable as substantiating a diagnosis, and it turned out to be markedly positive.

The alopecia quickly cleared up under neosalvarsan and mercury.

If one assumes, as seems reasonable, that the injury done to the shaft and follicle by a foregoing eruption is responsible for this patchy fall of hair, then the time of the incidence of the alopecia would indicate that the early cases would be due to an early eruption, and the later cases to a later eruption. For instance the alopecia of the first patient mentioned in this paper was coincident with a fading roseola, whereas the alopecia of the second patient, the negro, was coincident with the discoloration left by a papular eruption, which occurs several weeks later than the roseola. The fall of hair in both these cases occurred within the time usually set for it, that is, between the third and the fifteenth month.

The differential diagnosis of these cases of typical syphilitic alopecia is interesting. As has been mentioned, this symptom is almost pathognomonic of syphilis. A spotted alopecia, simulating this may be produced by pyogenic infection of the scalp, but in such cases either the affected area will be reddened in its entirety, or there will be a red spot in the center of the thinned out patch, or even a sear as a symptom of the foregoing pyogenesis. The scalp and the thinned out areas are usually free of pyogenesis when the alopecia is observed. That is to say, the alopecia is a consequence and a later development of a forerunning patchy pyogenesis, just as a syphilitic alopecia is subsequent to a focal disturbance due to spirochetes. It is principally seen in orphan asylums and other institutions for children, following an epidemic of impetigo.

Seborrhea will occasionally cause a fall of hair in one or two large patches. The patches, how-

ever, are large and few, and not scattered and numerous, and the seborrhea is well marked.

In alopecia areata the patches are usually much larger and less numerous than in syphilitic alopecia and they are sharply circumscribed and completely denuded of hair, the bald spot is dead white, and there are broken hairs at its edge if it is extending, and these hairs are "exclamation mark" shaped.

FIG. 2.

Pseudo-alopecia areata in a woman of fifty-three years of age, who has been under my care for five years. The process has been checked, but the bald places will remain irretrievably bald.

There is yet another disease that it is well to remember in a differential diagnosis,—the pseudo-alopecia areata of Brocq. In this there are scattered over the scalp a great number of irregularly shaped bald areas about the size of a finger print or less, separated by strands of sound hair. At first glance and at a distance the condition looks strikingly like that of syphilitic areolar alopecia, but on closely examining the bald spots themselves they will be seen to be slightly hollowed out, perfectly smooth, and with not a sign of a follicular orifice. The surface is cicatricial. Rarely an occasional hair will be left in the midst of such an area, but the patch remains definitely and irretrievably bald, as the hair follicles themselves are destroyed. This alopecia of Brocq comes on slowly, and assumes its spotted character after long years, it is absolutely atrophic, and the patches remain irreparably bald. It, therefore, is essentially different from syphilitic alopecia that comes on suddenly, and lasts only a few weeks, and in which the hair follicles can be seen to be intact.

In the foregoing it will be appreciated that, although typical areolar syphilitic alopecia is as simple as a symptom well can be, it is also almost as pathognomonic as a symptom can be, and that it may occur in a class of cases that may easily escape correct diagnosis, and therefore may remain untreated, with consequent increased danger of grave visceral syphilis supervening in later years.

NOTES OF A CONFERENCE ON THE MEDICAL AND SOCIAL ASPECTS OF SYPHILIS OF THE NERVOUS SYSTEM.

HELD AT THE PSYCHOPATHIC HOSPITAL,
MAY 27, 1915.

Social Worker.

APPENDIX A.

PSYCHOPATHIC HOSPITAL OUT-PATIENT DEPARTMENT

OUTLINE FOR HISTORY OF A PATIENT ADMITTED TO THE OUT-PATIENT DEPARTMENT.

Name of patient
Address

Age
Date and place of birth
Religion

Referred by
Brought to
Reason for bringing to the clinic
History given by

Family History

Father: Address, age, nativity, religion, occupation.
Mother: Same (maiden name).
Brothers and sisters: Ages, occupations, causes of
death if dead. (Still-births or miscarriages).
Husband or wife: name and birthplace, religion.
Date of marriage.
Children.

Heredity

Relationship between parents.
Condition of health, and cause of death, if dead, of:
Father
Mother
Paternal grand-parents; maternal grand-parents
Uncles and aunts.
Tbc., insanity, feeble-mindedness, epilepsy or can-
cer in family.

Social History

Time in U. S., in state.
Wage earners in family, and wages.
Character of home and neighborhood.
Patient sleeps with whom? Windows open?

Past History

Full term? Normal delivery?
Character of pregnancy.
Birth weight.
Feeding: Breast or bottle.

Age of sitting up
" " first tooth.
" " walking.
" " talking.
" " going to school.
Length of time in school.
School record.
Occupations (age, length of employment, wages).
Illness. Age of puberty.

Remarks

(To include as much information as possible about
the patient's character, habits and conduct, home
training and opportunities for development, his
associates and recreations.)

APPENDIX C.
 CARDS USED IN CATALOGUING FAMILIES OF SYPHILITIC PATIENTS.
 STYLE 1.—FIRST CARDS.

NAME	AGE		O. P. D. No.	
DATE	WASSERMANN: SERUM		FILE NO.	
RESIDENCE			FL.	
	AGE	DATE REPORTED	SERUM	FLUID
MOTHER				CASE NO.
FATHER				
SIBLINGS: 1				
2				
3				
4				
5				
6				
PERSON RESPONSIBLE				

For single patient.

NAME		AGE		O. P. D. No.	
DATE		WASSERMANN: SERUM		FILE No. FL.	
RESIDENCE					
	AGE	DATE REPORTED	SERUM	FLUID	CASE NO.
MOTHER					
FATHER					
SIBLINGS: 1					
2					
3					
4					
5					
6					
PERSON RESPONSIBLE					

NOTE.—By siblings is meant brothers and sisters in their relation to the patient. They should be recorded in order of birth, the oldest first. Stillbirths and miscarriages should be noted.

2. a. Single person, under 18 years, living with parents or with younger brothers and sisters.
- b. Every married person with or without children.
- c. Every unmarried mother, over 18 years, with children shall be put on the following type of card:

NAME		AGE		O. P. D. No.	
DATE		WASSERMANN: SERUM		FILE No. FL.	
RESIDENCE					
	AGE	DATE REPORTED	SERUM	FLUID	CASE NO.
SPOUSE					
CHILDREN: 1					
2					
3					
4					
5					
6					
7					
PERSON RESPONSIBLE					

NOTE.—Children should be recorded in order of birth, the oldest first. Patient should be indicated in numerical order with brothers and sisters. Miscarriages and stillbirths should be noted.

3. A card giving detail of work shall accompany both of the two types of cards shown above.

III.

ESTIMATE OF THE COST OF SOCIAL WORK IN CONNECTION WITH EXAMINATION AND TREATMENT OF OTHER MEMBERS OF FAMILIES OF SYPHILITIC PATIENTS THROUGHOUT THE STATE, BASED UPON 147 CASES DEALT WITH IN EIGHT MONTHS AT THE PSYCHOPATHIC HOSPITAL.*

BY MARY C. JARRETT, BOSTON,

Chief of Social Service Department, Psychopathic Hospital, Boston.

In the first eight months of prophylactic work for the families of syphilitic patients at the Psychopathic Hospital, the time given by the Social Service was equal approximately to one-half of the time of a social worker. The families of 147 patients were dealt with, 145 persons were brought to the Out-Patient Department for examination, representing 72 families among the whole number of families approached. In 25 cases all the members of the family were examined. For 35 persons treatment was given at the Psychopathic Hospital, and for 17 others, treatment was recommended elsewhere. On the basis of this work it may be estimated that one social worker on full time could deal in one year, or eleven months (allowance being made for the vacation period), with the families of 400 patients in the way indicated above, and described more fully by Miss Wright, social worker, in her paper on "Methods of Investigation." This estimate does not, of course, allow for social treatment of the cases, beyond securing the medical examination and blood test, getting a minimum social history, and giving advice about obtaining prescribed treatment.

If in special cases further services were required from the social worker, the time required for such work would have to be estimated according to the time needed for regular social case work.¹

It is possible that if the social worker undertook a smaller number of families than 400, by more persistent effort she might succeed in securing the examination of a larger number of persons. However, it must be expected that many of the families approached will not respond. In most cases there are difficulties in the way of the examination at the hospital to be overcome, such as: distance from the hospital, the inconvenience of staying away from work, absence from home, and most difficult of all, the objection of a seemingly healthy person to undergo an examination. This obstacle is increased

because it seems necessary in the present state of public sentiment in regard to syphilis that the social worker shall refrain from explaining the special reason for the examination and use only general expressions as to its desirability.

If 400 cases be taken as the number to be dealt with by one social worker in a year, and if the percentage of syphilitic patients among the insane, who are admitted to the state hospitals be taken as 20%, a need of half the time of one social worker is indicated for every 1000 admissions. At the Psychopathic Hospital, the percentage of syphilitics is estimated to be 15%, so that during the year October 1, 1913, to September 30, 1914, when the total number of new patients was 2666 (1853 first admissions in the House and 813 new patients in the Out-Patient Department) there must have been approximately 400 syphilitic patients, indicating that the time of one social worker should have been given to this form of prophylactic work.

The admissions for the same year to the other state hospitals from the community were 2783. As 21.1-3% of admissions last year were readmissions, the number of cases for this action would be somewhat reduced after the system had been installed. In the year 1913 to 1914, it may be estimated that one social worker on full time and another on half time would have been required to secure examination and treatment for the families of all syphilitic patients admitted to the state insane hospitals, so far as the persons approached could be induced to respond; and one additional social worker was needed for the same work at the Psychopathic Hospital.

IV.

A FEW ECONOMIC FACTS OF THE SYPHILIS PROBLEM, FROM THE PSYCHIATRIC SIDE.*

BY DONALD GREGG, M.D., BOSTON,

Assistant Physician, Psychopathic Hospital, Out-Patient Department.

DURING the calendar year 1914, 3039 new cases entered the Psychopathic Hospital,—1926 in the House, and 1113 in the Out-Patient Department.

Three thousand two hundred and thirteen Wassermann examinations of blood, or spinal fluid, were made during this year. Of this number, 780 were positive, or doubtful. These reactions appeared in 507 cases. Thus, in round numbers, among 3000 patients, 500, or 16.6% showed positive, or doubtful reactions for syphilis.

Further study of these 500 cases showed 208 of them to be suffering from general paresis.

* Being S. B. I. Contribution whole number 124 (1915.27).
Bibliographical Note.—The previous contribution was No. 123 (1915.26) by Helen M. Wright, entitled "Examination and Prophylaxis for Syphilitic Patients and Their Families: Methods of Investigation at the Psychopathic Hospital, Boston, Massachusetts, 1915." BOSTON MEDICAL AND SURGICAL JOURNAL, CLXXII, No. 24, 1915, p. 869.

¹ See "Further Notes on the Economic Side of Psychopathic Social Service," by Mary C. Jarrett, read at the Second Annual Conference of the Medical and Social Work of the Psychopathic Hospital, Boston, June 26, 1914. BOSTON MEDICAL AND SURGICAL JOURNAL, CLXXI, No. 23, Dec. 3, 1914.

* Being S. B. I. Contribution whole number 125 (1915.28).
Bibliographical Note.—The previous contribution by Mary C. Jarrett, entitled "Estimate of the Cost of Social Work in Connection with Examination and Treatment of Other Members of Families of Syphilitic Patients Throughout the State, Based Upon 147 Cases Dealt with in Eight Months at the Psychopathic Hospital," BOSTON MEDICAL AND SURGICAL JOURNAL, CLXXIII, No. 25, 1915, p. 921.

tabo-paresis, feeble-mindedness, epilepsy, or some other condition, presumably due to a syphilitic infection,—conditions that almost always need institutional care.

In other words, of the 3000 cases admitted to the House and the Out-patient Department, 500, or 16%, showed positive, or doubtful reactions for syphilis, and of these 500 cases, 200 were suffering from conditions due to a syphilitic infection and needing institutional care. That is, 200 out of 3000, or 6% of the total admissions were candidates for institutional care because of the results of syphilitic infection.

In the state institutions of Massachusetts, there were over 15,000 patients in 1913; 8.32% or over 1100 of these cases, were diagnosed as general paresis. Thus, this estimate of 6% for the Psychopathic Hospital is probably below, rather than the true status of affairs. But assuming that 6% is a fair figure, this means that in the state of Massachusetts, some 900 individuals are in state institutions, and in part or wholly, state charges, as a result of syphilitic infection.

It costs some \$223.60 per annum to support an inmate of a state institution. At this rate, over \$20,000 is spent in one year to care for individuals who are suffering mentally as the result of syphilitic infection.

A dose of salvarsan now costs \$5.00. It is estimated that ten doses might have some beneficial results in treatment of cases of this sort. This means \$45,000 for salvarsan alone if treatment is undertaken for these cases.

If one automobile kills, or totally incapacitates a man, a lawyer tells me that \$5000 is an average amount paid for damages. At that rate, \$4,500,000 is the damage that the spirocheta has done to the 900 patients in the state institutions of Massachusetts.

As you know, syphilis is not a disease that affects an individual alone. It is visited upon his children. Complete records of the family histories of these cases were not to be had. Among 70 cases, however, 133 deaths in the families were recorded, 52 miscarriages and 8 stillbirths—a total of 193. If these children's deaths were due to syphilis, and if this ratio holds throughout all the cases, 2490 children born and unborn, related to the patients in state institutions in 1914, have died from syphilis. And yet it is known that women having syphilis of the nervous system, do not miscarry nearly as frequently as do other syphilitics. Consequently, no one has any knowledge of how many infants and children die each year in Massachusetts as a result of syphilis.

Lest it be thought that syphilis is a disease of the poor and socially inefficient, the following list of occupations is given which were noted among the occupations of these patients:—

1 Architect	1 Banker
1 Accountant	1 Insurance Agent
1 Store-keeper	1 Stenographer

2 Jewellers	1 Solicitor
1 Journalist	1 Policeman
1 Ship Chandler	1 Wool Broker
1 Photographer	1 Clergyman
1 Blue Printer	1 School Manager
1 Farmer	1 Bank Clerk
1 School Teacher	1 Superintendent of Electrical Co.
1 Milliner	1 Physician
5 Traveling Salesmen	
1 Actor	

Lest it be forgotten that the community may be endangered by the inefficiency of these individuals—inefficiency that may develop without warning—the following list is given of some of the potentially dangerous occupations of these patients:—

3 Engineers	1 Boat Captain
2 Druggists	1 Railroad Signal Man
3 Electricians	1 Car Inspector
2 Conductors	1 Motorman
1 Janitor	1 Lighthouse Man

And lest we forget how close home this disease may be brought to all of us, this list of occupations of these patients is given, although it is to be remembered that only under certain conditions and in certain stages of the disease, is it strongly contagious:—

7 Waiters	1 Nurse Maid
1 Trained Nurse	1 Fruit Peddler
5 Barbers	1 Milkman
3 Caterers	1 Grocer
2 Cooks	

These are some of the economic facts regarding this disease as seen at a hospital for mental diseases.

In New York City last year, during a period of 14 weeks, syphilis stood first in the list of infectious and contagious diseases, with 28% of the total number reported; tuberculosis was next, with 21%, and afterward, diphtheria, measles and scarlet fever, in the order named.

We all know what is being done to eradicate tuberculosis, which maims the body of the individual; but syphilis, which maims both body and mind, and is visited upon the generation yet unborn, is scarcely mentioned in the public press because many of the cases are venereal in origin.

(To be continued.)

Clinical Department.

FRACTURE OF THE TRANSVERSE PROCESSES OF THE FIFTH LUMBAR VERTEBRA.

By LLOYD T. BROWN, M.D., BOSTON.
AND
W. J. DODD, M.D., BOSTON.

A GREAT deal of attention lately has been given to the lumbar and lumbosacral spine as a cause of backache. In any large series of x-rays, such as one sees at the Massachusetts General Hospi-

tal, one occasionally finds some x-rays that show breaks in the continuity of the transverse processes of the lumbar vertebrae. Six cases of this kind were reported by Rhuyts, under the title of "Pseudo Fractures of the Transverse Processes." He believes that they are due to a non union of the epiphysis in this region and are not true fractures, and bases his opinion largely on the fact that in his cases there were no histories of any injury severe enough to cause a fracture. The following case is reported with x-rays to show that this condition may occur without violent trauma and may be a true fracture.

On August 30, 1913, the patient, age 42, a medical man, gave the following history: When in college he had to stop playing football because of backaches coming on after getting tired. If he did not get overtired he had no trouble. For the past twelve years he had been treated for tabes, the diagnosis being made by some of the best medical men and neurologists. The chief symptoms were backache and leg pains associated with absent knee jerks. Argyl Robertson pupils and an increasing ataxic gait. This condition and the distress with it gradually increased until the attempts to control the pain with morphia caused the still more distressing troubles of a morphia habit. The patient, seven months ago, went through a course of treatment to stop the morphia. This was successful but left him in a very much relaxed and weakened condition. He then went to an out-of-door physical culture establishment, where in about three weeks he was brought to a condition of being able to walk six to eight miles or more a day. Part of the training was riding horseback. One day, being extremely tired and relaxed, he received, while riding, a sudden jolt which caused a moderate amount of pain in his back. A few days after this ride the masseur told him that the lower back was black and blue. It was also somewhat sensitive to pressure. For ten days following the ride, the pain in his back and legs, first one and then the other, depending on certain motions being made, increased so that he had to stop the training. When the examination was made two weeks after the injury, it showed a large tall man, of the broad heavy type, of muscular but somewhat flabby build. He had a distinctly ataxic gait. He had had a great many Wassermann reactions done, none of which had ever been positive, not even from a lumbar puncture. The standing attitude was one in which there was a very marked increase of the normal lumbar curve, associated with rounded shoulders and a forward position of the head. There was considerable limitation of the lateral spinal motions—especially in the low lumbar region. Flexion of the spine showed that the lumbar curve could be made flat but not rounded. There were two definite points of tenderness just inside the posterior superior spines, at the place where the transverse processes of the fifth lumbar vertebra should be. An x-ray, taken by Dr. Walter Dodd, two days after the above physical examination (see Fig. 1) showed large, broad transverse processes of the fifth lumbar vertebra; a sacrum which was placed low between the crests of the ilia. This meant, of course, that, if there should be much hyperextension of the spine on the sacrum, these transverse processes would be more liable to impinge either on the ilia or on the wings of the

FIG. 1.—Note the fracture of the transverse processes of the fifth lumbar vertebra: That the lumbar vertebrae are large and are broad compared to their height. That the transverse processes are also of the large broad type. That the sacrum is placed low between the ilia.

sacrum. These transverse processes, in the x-ray, showed a definite break of their continuity. The edges of the break were serrated and closely resembled a fracture. A diagnosis was made and confirmed by Dr. Dodd of probable fracture of the transverse processes of the fifth lumbar vertebra. The treatment was planned to support the lower lumbar region and to correct the markedly increased lumbar curve with the hope that by so doing, the strain on the fifth lumbar transverse processes would be relieved. A belt with a pad to bridge the lumbar curve behind and a pad to hold up the abdomen in front was applied. In three days there was a marked lessening of the pain down the legs and the patient also thought the ataxia was less marked. Fig. 2 shows a second x-ray taken three and one-half

FIG. 2.—Taken three and one-half months later, shows a callus formation at the sites of fracture.

months later. This shows a thickening of the edges of the bone around the break in continuity, which

closely resembled callous formation. With this change in the x-ray picture has come a relief of the symptoms of which the man complained, namely relief from the pain in the back and legs and what is still more interesting, a marked decrease of the ataxic gait.

Whether there is any connection between the ataxia and the possible pressure which may have been produced by the anatomy of the spine in the lumbo-sacral region, combined with the faulty posture, is a matter of conjecture. We report this case, as it may interest others as it has interested us.

FIG. 3.—Taken sixteen months after Fig. 1; shows the callus somewhat smaller than in Fig. 2.

We wish to thank Dr. Goldthwait for permission to report this case.

A CASE OF DERMATITIS MEDICAMENTOSA.

By WILLIAM S. WALSH, M.D., PROVIDENCE, R. I.

THERE is scarcely a drug in the pharmacopeia that may not produce a skin eruption when such a drug is administered to a susceptible person. Moreover the eruption produced may be macular, papular, vesicular, pustular, bullous, ulcerative, gangrenous, diffusely erythematous, or urticarial, and may simulate certain definite diseases of the skin, or conform to no well recognized type. The same drug may produce a variety of skin disorders, so that, with the possible exceptions of silver, arsenic and the bromides, they present, clinically, nothing specific in their various manifestations.

Generally, drug eruptions occur most commonly in persons whose vitality is low, or who are nervous subjects. Constitutional or organic disease, as well as idiosyncrasy, are predisposing factors. The eruptions are usually bilateral, appear mostly on the exposed surface of the

body, are not accompanied by fever as a rule, generally do not itch, are not painful, save in severe inflammatory types, appear suddenly, disappear rapidly on cessation of the drug, are very red in color, and have atypical courses.

It should be the practice of every physician to inquire of his dermatological patients whether or not they have been taking medicine. In this way many an embarrassing situation will be escaped. Only lately I saw a young child, who, on cursory examination, seemed to be undoubtedly suffering from scarlet fever. He was profusely covered by a scarlatiniform rash, had a temperature of 102, a rapid pulse, enlarged cervical glands, etc. When the facts were considered, namely, that generalized, scarlatiniform drug eruptions are often accompanied by systemic disturbances and a rise in temperature, that the child was tubercular and had been receiving atropine for a corneal ulcer, the original diagnosis of scarlet fever was changed to one of belladonna eruption.

In this connection I wish to describe briefly a case of mercury eruption following a short course of vaginal douches.

The patient was a strong robust girl, aged 21, single, white, who presented herself for treatment on April 8, 1915, being over eight months pregnant and having a very profuse vaginal discharge due to the gonococcus. She had a large condylomatous mass on the left vaginal wall which refused to respond to therapeutic measures until after delivery. She was placed under treatment with daily douches of bi-chloride of mercury, two quarts of a 1 in 5000 solution being employed. This treatment was kept up until May 25th, on which day she was delivered of a normal male child. The douches were discontinued until July 19th at which date they were again instituted. On July 24th the patient developed redness on the sides of the nose, her temperature rising to 103.8°. On the following day a diagnosis of erysipelas was made. On July 27th she complained of a bad taste in the month, of salivation, and sore teeth, small pieces of which were chipped off. The douches were discontinued. On July 28th her temperature was 99, on which day she developed a generalized eruption. The eruption was papular, slightly scaly, intensely inflammatory, did not itch, and was not accompanied by any marked subjective sensations. A few tiny vesicles surmounted some of the papules. The lesions varied in size from a small pea to a dime. A Wassermann reaction taken sometime previously was negative, so there was no doubt but that the eruption was due to mercurial poisoning. A few days after the cessation of the douches it disappeared. Unfortunately the patient soon after left for other parts, so her reaction to mercurial preparation by mouth could not be tested.

We know that mercury may cause erythematous, furuncular, herpetic, papular, purpuric, pustular, scarlatiniform, ulcerative and urticarial lesions, but the rarity of eruptions from the absorption of mercury, and especially the production of an eruption by way of the vagina, prompt me to offer this case as a contribution to the meagre literature on the subject.

A CHEMICAL AID IN SECURING THE SPIROCHETA PALLIDA FROM SYPHILITIC LESIONS.

BY HENRY D. LLOYD, M.D., BOSTON.

[From the South Medical Department, Massachusetts General Hospital.]

SOME four months ago in a short monograph* we came across the statement that alcohol applied to any ulcerated specific lesion, either primary or secondary, increased greatly the number of recoveries of the spirocheta pallida. Since that time our method in the South Medical Department at the Massachusetts General Hospital has been the following:—

First carefully to clean the lesion, using water or salt solution, and then to wash it with 95% alcohol. This is only slightly painful. Then by lateral pressure we almost always secure a most abundant supply of serum, presumably serum from the deeper layers; for since we have been applying alcohol to the primary lesion or the ulcerated secondary lesion our percentage of recoveries of the spirocheta pallida has averaged at least 95%. It is impossible to say what the percentage of recoveries was before the use of alcohol, but we estimate it at least 20 or 25% less.

* The Salvarsan Treatment of Syphilis in Private Practice. By George Stopford-Taylor and Robert Wm. Mackenna.

Harvard Medical School.

LEGAL MEDICINE.*

I.

It is obviously impossible to give in a few lectures all that a Harvard graduate in medicine should know about legal medicine. Thus the practical and immediate object of these lectures is to present some of the situations which are likely to arise in the practice of medicine and to discuss some of the principles in the relations of the law to medicine.

Legal medicine is not a specialty in medicine, but rather medical science in all its branches viewed from a particular angle. The law's requirements of practitioners of medicine may be divided into:

(a) Service which medical science must give to the law, of which the following are examples:

- (1) The determination of the sex of a malformed infant.
- (2) The determination of the sanity or insanity of an individual.
- (3) The discharge of the duties of an ordinary medical witness.

(b) Proper conduct as physicians in the case of patients and the maintenance of public health, of which the following are examples:

- (1) Compliance with registration laws in regard to birth, death, and reportable diseases.

- (2) Avoidance of unlawful acts, malpractice, etc.
- (3) All conduct in connection with occupational diseases and the hazards of labor.

The Registry Laws—The Death Certificate.

(a) The importance of the death certificate is very great in that it forms one of the essential sources of information for vital statistics. Uniform procedure in obtaining death certificates protects the community against all manner of crime and irregularity. The statute law requires the physician in attendance on the final illness to state the cause of death.

(b) The cause of death not always correctly given. Doctors should adhere to the standard form recommended by the bureau of the census with the list of accepted causes of death. A clear distinction should be drawn between primary and secondary causes of death: e.g. broncho-pneumonia might be immediate cause of death but antecedent measles would be the correct primary cause of death.

(c) A physician should not take the full responsibility of signing the death certificate under any of the following conditions:

(1) If the attending physician has not seen the patient within two weeks before death. Board of Health regulation provides that he may sign the certificate if he has seen the patient within two weeks before death; otherwise he should call up the Board of Health and obtain special authorization to sign the certificate.

(2) If the fact of death be in any doubt. The undertakers being in no way controlled as regards time of embalming, it is essential that bodies be withheld an adequate time to prevent any mistakes on the fact of death.

The signs of death are: (a) Cardiac and respiratory failure, (b) Loss of heat and rigor mortis. Here temperature of the room must be considered. Rigor very slight in aged or after wasting fevers, etc. (c) Post-mortem lividity. Distinguish between normal lilac color and the bright red of CO (gas or charcoal) poisoning.

(3) If there is any contributory factor of accident, trade disease or other abnormality. For example, death from hypostatic pneumonia following fracture of the hip from a fall should not be reported without notifying the medical examiner. Trade diseases under the Workingmen's Compensation Act are especially important.

(4) If the death is due to acute alcoholism or delirium tremens.

(5) If the death occurs under medical observation of so short a duration that the etiology is in question, the medical examiner should be notified.

* Lectures by Dr. George B. Magrath at the Harvard Medical School, Nov. 26 and Dec. 3, 1915.

- (6) If sudden death occurs in the presence of several competent witnesses, in a patient not under previous medical observation, the medical examiner should be notified or the undertaker should be referred to him for the death certificate. The body may be moved before the arrival of the medical examiner, if the character and number of the witnesses is sufficient.
- (7) In persons found dead, or where no adequate number of persons witnessed the death, the medical examiner must be notified. The body should not be disturbed in its position, if any such change is likely to destroy evidence in regard to the manner of death.
- (8) If death occurs following the administration of anesthetics in operations which are not long or exhausting, it is the province of the medical examiner to investigate the exact cause of the death.
- (9) If the death be due obviously or presumably to any form of injury.

Dying Declarations.

These statements are of considerable legal value as testimony and as they are also subject to the physician's influence they form an important part of medico-legal study. It is important to secure a dying declaration whenever the testimony thus given has an important legal bearing on the fixing of responsibility for the expected death. That a patient in a grave condition could be worried by persistent efforts to wring a dying declaration from him, to so great an extent as eventually to cause his death, is well recognized by the law. The attending physician therefore is given the authority to limit the extent of questioning, etc., to which the patient shall be subjected. In order to be valuable legal testimony the dying declaration must contain statement by the patient to the express effect he believes the statement to be his dying declaration. The attendant physician is responsible for the diagnosis of the condition of patient who makes a dying declaration to him.

The Office of the Medical Examiner.

Since earliest times under English law there has existed the office of coroner, which was occupied by men who investigated the causes and circumstances of deaths primarily to ensure that the proper portions of the deceased's estate became the property of the Crown. Also, it is mentioned, the coroner had direct authority over the disposal of "whales, sturgeon and other royal fishes" and was wreck-master in general throughout the realm.

At present in most states in this country the coroner system is in force. Under this plan the coroner is a peculiar mixture of investigator, magistrate and doctor, with the authority (but not always the ability) to establish scientifically the cause of death, to investigate sufficiently the manner and circumstances of death, and to take adequate measures for fixing the legal responsibility. The ordinary procedure in cases of death due to other than natural causes is for the coroner to take charge of the body, hold a view, make inquiry as to the manner and circumstances of death. If he is satisfied here,

he may pronounce the case as one not needing further investigation. Or he may impanel a jury, submit the facts to them and charge the jury to declare whether the death was due to murder or not and to find, if possible, the murderer.

Since 1878 Massachusetts has made the distinct office of medical examiner, transferring the magisterial power to the criminal and civil courts. All deaths due to causes other than "natural" disease, are now subject to the investigation of the medical examiner. There is no law that requires the physician to summon the medical examiner, but there is a law requiring that no burial permit be given in case the death was due to violence, accident, occupational hazard, or causes other than natural disease, save on the certificate of the medical examiner.

G. B. MACRATH, M.D.
A. GREGG, A.B.

II.

1. The Definition of Sudden Death. It is important that the practitioner know what legally constitutes sudden death, for in such cases his responsibility may become medico-legal. A sudden death is defined as a death of a person not disabled by recognized disabling disease. Sudden death does not mean unexpected death. Sudden thrombosis followed by death in a case of typhoid would not be considered medico-legally as sudden death.

2. Rapid Deaths are most commonly due to:

- (a) Heart disease. Chronic valvular disease, myocarditis, or coronary sclerosis can all exist without external symptoms or signs previous to rapid failure and death. These cases always appear in increased numbers during the first cold weather, when slightly increased early morning exertion, running against the wind, etc., brings on rapid and fatal decompensation.
- (b) Status lymphaticus. This condition, recognized usually only anatomically post-mortem, is seen in connection with sudden death in young individuals upon administration of sera or primary ether. It is a mistake to assume that all traces of thymus are gone by maturity, for enlargements are found at various ages up to middle life even.
- (c) Thrombosis and embolism. Cerebral embolism is very rare. Pulmonary embolism is always consequent upon thrombosis on the systemic side of the venous circulation. The usual signs are cyanosis, pain in chest and respiratory distress, and death ensues in a few minutes to half an hour.
- (d) Acute hemorrhagic pancreatitis. Always associated with severe abdominal pain, and though death is rapid it is not instantaneous.
- (e) Apparently many physicians are unaware that the chronic use of distilled liquors may give very rapid death. For some reason this death, due to "wet brain", is very swift, and is usually preceded by syncope.

- (f) Cerebral hemorrhage is not properly in the list of the causes of rapid death, as ordinarily death does not take place before two hours are past.

Medico-Legal Aspects of Abortion.

- A. The subject of abortion is important to the practitioner in that its legal aspects concern (1) his rights as an obstetrician and gynecologist, and (2) his conduct in case he be hurriedly summoned to attend a patient with symptoms of miscarriage threatened or completed.
- B. The legal definition of abortion is "any interruption of the normal period of gestation of ten weeks", and no distinction is made between abortion, miscarriage and prematurity. Under such a definition are grouped two classes (a) natural abortion, and (b) induced abortion, and again under (b) (1) therapeutic induced abortion, and (2) criminal abortion. Under (a) for example would fall the abortions due to placental disease, strangulation of the cord, etc., and other "innocent" abortions.
- C. Induced abortion is due to external agents, either medication or instrumentation. The important distinction is between such abortions as could be justified as therapeutic measures and those which are directed against the life of the foetus.

- (1) Therapeutic abortions may be indicated:

(a) In the eighth to ninth month on account of pelvic dystocia or anomalies of foetal development. The increasing success and safety of the Caesarean qualifies the validity of such reasons.

(b) Whenever the continuance of the mother's life is conditioned by terminating pregnancy.

(c) Any condition in the mother which in the opinion of two or three reputable physicians necessitates the interruption of pregnancy. *E.g.* pernicious vomiting.

There is no law in black and white as to when abortion may be induced and when not. It is wise to consult usually the woman, always her husband and two other physicians. Three reputable physicians concurring in the opinion that a woman should have an abortion done would render the situation legally sound.

- (2) Abortions are criminal when there is intent to produce miscarriage maliciously, *i.e.* with malice directed against the life of the foetus. The law says nothing of the destruction of foetal life, it is not

an infanticide law but one directed against the attempt to cause miscarriage. The mother inducing abortion on herself assumes the same legal status as does the man practising criminal abortion; the Massachusetts law provides a penalty of not less than five nor more than 20 years' imprisonment if the abortion is followed by death, otherwise a penalty of not less than one or more than seven years, or a fine of \$1000. Convictions for criminal abortion are rare among physicians, and sentences for self-induced abortions are very rare. Probably abortion is very frequent, but the spreading knowledge of rudimentary asepsis has reduced the morbidity and mortality in the last 20 years.

- D. The detection of criminal abortion depends largely on finding the instrument used, or on determining the type of medication employed. Poisoning by medication is rare and hence, when mechanical means may be also ruled out, it is sometimes hard to find the cause. Instrumentation is much the more common and includes a wide variety of objects. Remember that air from syringe irrigation has been known to be fatal. The two most serious complications are retained membranes and perforation of the uterus.

The Relation of the Regular Practitioner to a Case of Abortion.

I. Transfer to hospital. If it be a public hospital, give a full account of the case to the admitting physician; if a private hospital, call in consultation, one at the least and preferably two, consultants. Hospital is the best place—for the doctor to have the patient.

II. If patient doesn't go to hospital, call in two consultants.

III. If the evidence points to induced abortion it is prudent for the physician to apprise the medical examiner.

IV. If serious complications set in, get a statement from the patient. If, without being too much of a police officer, it seems best to fix the responsibility, then notify the bureau of criminal investigation and they will take charge of the entire case.

V. In the case of the physician being called upon to dispose of the foetus, it is customary to treat as stillborn any foetus one foot long and weighing $1\frac{1}{2}$ pounds. Stillborn babies require certificates for burial. Foetuses under $7\frac{1}{2}$ months may be treated as surgical product. The main legal question being the viability of the foetus, it is obviously safe for physician to take complete charge of the extremely premature foetuses in all cases which are open to no question.

A. GREGG, A.B.

Book Reviews.

Occupational Affections of the Skin. By R. PROSSER WHITE, M.D., Edin.: M.R.C.S., Lond. New York: Paul B. Hoeber. 1915.

The author of this brochure states that his own requirements prompted the compilation of the facts contained in it, and that he claims for it only a needed assistance for the English enquirer. He justly says that complete data are difficult of access, as they are very much scattered in foreign and English periodicals. The book will be, as its author intended, a help. It is not the last word on this subject, but besides the partial aid it will afford to dermatologists and general practitioners, it will serve as a help to future compilers of the data of this subject. The few illustrations are hardly worthy, either in execution or importance, of the general merits of the book.

Diseases of the Skin and the Eruptive Fevers. By JAY FRANK SCHAMBERG, M.D., Professor of Dermatology and Infectious Eruptive Diseases in the Philadelphia Polyclinic and College for Graduates in Medicine. Third edition, revised. Octavo of 585 pages, 248 illustrations. Philadelphia and London: W. B. Saunders Company. 1915.

Schamberg's third edition has been revised to meet the more important advances in dermatology since the appearance of the last edition. He has given the prescriptions, both in the metric and Troy systems in this edition, and has inserted a chapter on the Luetin Test in Syphilis, as well as rewritten the chapter on the Therapy of Syphilis, to conform to present day beliefs. As before, the most original and interesting part of his work is his chapters on the eruptive fevers, and an important addition has been made to the discussion of the mild type of smallpox, which is so often unrecognized. There is also a brief chapter on Rocky Mountain spotted fever, together with a photograph. Most of the illustrations are excellent.

Diseases of the Arteries. By SIR CLIFFORD ALBUTT, K.C.B., M.A., M.D., F.R.C.P., F.R.S., LL.D., D.Sc., Regius Professor of Physic in the University of Cambridge, England. In two volumes. London: Macmillan and Company, Ltd. 1915.

This elaborate work, by a distinguished leader of the British medical profession, is perhaps the most extensive study of arterial diseases that has yet appeared in the English language. It has evidently been in preparation for some years,

and was delayed by the outbreak of the European War. This, however, led also to the author's return to active practice, and thereby indirectly stimulated the completion of the work and supplied new material for its augmentation.

The first volume and a small part of the second are devoted to arteriosclerosis, with the report of elaborate clinical and experimental observations on its causes, symptoms, pathology, diagnosis, prognosis and treatment. The remainder of the second volume is devoted partly to aortitis, with its sequel of aneurysm, and partly to angina pectoris, with its various etiologies and manifestations. The book is not illustrated, but has an excellent index and constitutes a valuable and authoritative contribution, representing the extensive professional experience of one of the leaders of the British profession.

Hand-book of Physiology. By W. D. HALLIBURTON, M.D., LL.D., F.R.C.P., F.R.S. Twelfth edition. Philadelphia: P. Blakiston's Son and Company. 1915.

The eleventh edition of this standard textbook by the professor of physiology at King's College, London, was published in 1913. At that time considerable changes were made from the previous edition, especially in the sections on salivary secretion, urinary excretion, respiration, conduction of the heart, application of physical chemistry to physiology, vitamins and reproduction and development. In this twelfth edition, which is at the same time the twenty-fifth of Kirkes' Physiology, the older work upon which this is based, only minor alterations are made. The work is illustrated with 577 text figures, many of which are colored, and with three colored plates. It should continue to maintain its usefulness as a manual for students.

A Text-book of Chemistry and Chemical Urinalysis for Nurses. By HAROLD L. AMOSS, S.B., S.M., M.D., D.P.H. Philadelphia and New York: Lea and Febiger. 1915.

This text-book in elementary chemistry for nurses contains not only the principles of inorganic and organic chemistry, but the application of these principles to the chemistry of the body, particularly with reference to the study and analysis of the various secretions. It is perhaps questionable how much of this knowledge is a desirable or necessary part of a nurse's education, at least during her training school years; but the book presents the facts of chemistry in convenient, well ordered and readily comprehensible form and should prove useful and available in the instruction, not only of nurses, but of other preliminary students in chemistry.

The Care of the Baby. By J. P. CROZER GRIFFITH, M.D., Professor of Diseases of Children in the University of Pennsylvania. Sixth edition; thoroughly revised. Illustrated. Philadelphia and London: W. B. Saunders Company. 1915.

This, the sixth edition of this well-known work, the first edition of which appeared in 1895, maintains the high standard of its predecessors. It has been thoroughly revised, reset and reprinted. In spite of the many books dealing with this subject which have been written during the past ten years, this book continues to be one of the best, if not the best, of them all. It is full of good sense, tells the mother in plain language what she ought to know, and does not attempt to usurp the place of the physician.

The Practical Medicine Series. Under the General Editorial charge of CHARLES L. MIX, A.M., M.D. Vol. IV, Gynecology, edited by EMILIUS C. DUDLEY, A.M., M.D., and HERBERT M. SOWE, M.D., Chicago: The Year Book Publishers. 1915.

This fourth volume in the Practical Medicine Series of 1915 aims to present the progress of the preceding year in gynecology. The subjects are treated in a series of brief essays, grouped under six appropriate captions. The book is illustrated with sixteen full page plates and two-text figures. It constitutes a serviceable review for the practitioner of recent advances in gynecological practice.

Simplified Infant Feeding. With seventy-five illustrative cases. By ROGER H. DENNETT, B.S., M.D., Adjunct Professor of Diseases of Children, New York Post-Graduate Medical School; Attending Physician of the Children's Department, New York Post-Graduate Hospital; Assisting Attending Physician at the Willard Parker Hospital and the Red Cross Hospital, New York. With 14 illustrations. Philadelphia and London: J. B. Lippincott Company. 1915.

The author in his preface states that he believes in a definite method of infant feeding and does not believe in individualization in feeding. He also states that he does not believe that it is necessary or advisable for the physician to be acquainted with the "theories" of infant feeding and that it is better to tell him in detail just how to feed an infant by rule. Believing, as we do, that the author is absolutely wrong in his

premises, that it is impossible to feed babies by rule, that individualization in feeding is necessary and that the more theory the practitioner knows the better he can feed babies, we cannot, of course, approve the book as a whole.

The author's scheme of feeding is briefly somewhat as follows: Believing that 4% of fat is not easily digested by the average infant, he gives 1 1/3% or 2% of fat by simple dilution of cow's milk. He makes up the deficiency in fat with sugar. He believes, however, that sugar is the most frequent source of indigestion of any of the elements. He advises cane sugar for older infants and for those with no intestinal or gastric indigestion and malt sugar for infants which have had much intestinal trouble. Milk sugar should not be given at all. He discards the former methods of making the proteids more digestible, such as whey mixtures, the addition of lime water and cereal gruels, and says that boiling the milk is all that is necessary to make the proteids digestible, and that it has now supplanted the other methods. He believes that the proper quantity of food is best estimated by caloric standards. In order to determine the caloric needs he multiplies the weight of the baby by the caloric requirements per pound. He gives one ounce of sugar in twenty-four hours to babies weighing less than ten pounds and one and one-half ounces to those weighing more than ten pounds. After subtracting the calories given by the sugar he adds enough milk to cover the caloric needs. He divides the number of calories needed by 20 to find out the number of ounces of milk required. He then adds water to make up the required amount of food. He gives, however, a number of conditions under which the caloric requirements should be ignored. He recommends six or seven feedings in the twenty-four hours. He apparently believes in giving a raw food unless there is some special indication for boiling. We disagree to a greater or less extent with all of the author's statements and methods as given above. This is not the place, however, for a long discussion of the subject of infant feeding.

Certain portions of the book are worthy of the highest praise, however. The directions given as to the taking of histories and for physical examination are admirable. The chapters on breast feeding and the treatment of constipation are also very good. The detailed descriptions given as to methods of feeding and the preparation of the food are also admirable. His classification of the diarrheal diseases and of the disturbances of digestion is, on the whole, good, although the terminology is somewhat different from that used by the reviewer. He recognizes that these disturbances and diseases may be due either to errors in the diet or to bacteria. The treatment is, on the whole, rational, except in so far as it is modified by the author's peculiar views on infant feeding.

The illustrations are original and remarkably good.

A NEW METHOD OF TABULATING MORBIDITY STATISTICS IN THE MEDICAL DIVISION OF THE HEALTH DEPARTMENT OF THE CITY OF BOSTON.

SINCE Sept. 1, 1915, the Boston Health Department has been using electric sorting, counting and punching machines in the compilation of morbidity statistics. Formerly all the mortality statistics published by the Health Department have been compiled by this system. Beginning this year a study was made to see if the same machines could be used to furnish the morbidity statistics. The system of records formerly in use called for many different ledgers and separate units and cabinets for holding the different cards and records, so that it was impossible to collect under one unit the different data necessary for the compilation of the statistics; and to obtain any special information concerning any particular disease entailed the work of days and sometimes weeks on the part of the

clerical force. Under the present system a separate envelope has been devised (a different color for each disease), on the face of which all the necessary data are recorded from the beginning to the end of the case. Within this envelope is held the original reporting card of the attending physician, the card of the visiting medical inspector, and the card of the visiting nurse, thus keeping all the records relating to each case together, and all the envelopes filed in one cabinet, instead of being distributed among several books and card indices as in the old system. This information is then punched on a special card, and this card carries with it a complete history of the case. A code has been made, and numbers assigned, for some of the more important facts.

Diphtheria, tuberculosis, scarlet fever, typhoid fever, measles, whooping cough, and ophthalmia neonatorum are diseases in which it is all-important to have the necessary information on each and every case, in order that effective measures may be taken for their control. During the past few months that this system has been in use, it has demonstrated to the satisfaction of the department the accuracy of the data furnished and the great saving in time and labor on the part of the clerical force. Where heretofore it was impossible to furnish quickly the necessary information regarding the health conditions or morbidity rate of any district, now it is only a question of a few minutes when this information can be furnished to those desiring the same. For example, it may be asked, "what are the health conditions of some particular ward of the city as regards tuberculosis?" By means of our punched card system and the use of the machines, information can be given as regards the number of cases in any particular ward of the city; date reported; sex; age; kind of house, whether single or several apartments, hotel, lodging house, institution, basement; sanitary condition of house; birth-place of patient; occupation; whether two or more cases in the family; number of other cases in the house; laboratory findings, whether sputum is positive or negative; whether patient is confined to hospital; if at home, whether in a separate room, and duration of illness (in case of death).

In diphtheria, information is punched as regards date reported; age; ward; school attended; whether antitoxin was administered; whether confined to hospital; occupation; sex;

milk supply used; number of other cases in the house; kind of house; laboratory findings; and date of release.

In all other diseases the same method is in use. All the facts necessary are punched on the card. These cards, fed to the machine, furnish accurately within a few minutes all information desired.

One of the great advantages of this system that has been found since it has been installed is that no case once reported to the department can be released until all the necessary facts are made a matter of record. Under the old system, when an audit of the cases was made at the end of the year, some very important data necessary for the morbidity and mortality statistics were found missing, and so much time had elapsed it was impossible to obtain the necessary information on these cases.

By the use of these machines and the card system it will be possible for this department to furnish at any time the morbidity statistics of this city, and especially to publish at the beginning of the year the annual report, which will show the activities of the department and the morbidity rate of the city either as a whole or in the different districts. Under the old system it was impossible to publish this report until several months had elapsed.

MEDICAL LEGISLATION: AN UNJUST BILL.

WITH the national congress convened at Washington, and with the session of the state legislature beginning in Boston next month, the legislative season is again at hand with possibilities, good and bad, affecting the medical profession and its work, like other classes and activities. Alertness on the part of physicians, individually and collectively, is essential to prevent, if possible, the passage of injudicious or unjust legislation and to promote the passage of desirable legislation, which, without their advocacy, might fail of enactment.

During the coming legislative season, the JOURNAL will, as in the past, undertake to comment editorially from time to time on such matters of medical legislation as seem to deserve the particular attention of the profession, aiming to present both sides of every question, to reflect expert opinion on the subject in hand and, where it seems fair to reach a positive decision,

to indicate the opinion which it believes physicians should take. In doing this it will speak without fear or favor, but will aim always to allow due weight to opposing aspects of every question.

Among the bills already filed with the clerk of the House of Representatives of the Massachusetts General Court for the coming season is the following proposed measure making it obligatory for physicians to render professional services under all circumstances when asked to do so.

"It shall be unlawful for any physician or surgeon to fail to render his professional services to any sick or injured person in need of such services, as promptly as circumstances permit, provided that he is so requested by, or in behalf of, the sick or injured person, that he is not prevented by illness, absence, professional engagements or by any other unavoidable cause, from rendering such service, and provided that the sick or injured person is at the time in the same city or town in which the physician or surgeon practices.

"Refusal or neglect by any physician or surgeon to render professional service, when so requested, to a sick or injured person then being in the city or town in which the physician or surgeon practices, shall be considered as a violation of this act unless it is affirmatively shown by the defendant that such refusal or neglect was unavoidable as above defined.

"For any such service as is required by the provisions of this act, the physician or surgeon rendering the same shall be entitled to receive and may recover reasonable compensation, and if the compensation is not paid within six months by the patient or some one in his behalf, it shall be paid by the city or town in which the service was rendered.

"Violation of this act shall be punished by a fine of not less than \$5 or more than \$100."

This bill seems not only unreasonable but unjust. It is presumably aimed at physicians who, for sufficient and obvious reasons, decline to attend cases of criminal or dubious abortion, or patients who have already been in the hands of other practitioners. When other medical aid is available, and the patient therefore will not suffer, such a course seems wholly justifiable. Neither do we believe it just that the community should be made responsible for medical debts incurred by its irresponsible members. No reputable physician would refuse to attend any case, when no other consultant could be obtained within a reasonable time. The honorable freedom of the profession should not be restricted by such a piece of unwarrantable compulsory legislation. If physicians can be trusted

at all with the responsibility of human health and life, their ethics and humanity may be relied upon to prevent them from ever really jeopardizing or allowing a patient to suffer when other medical care cannot be obtained.

MILITARY TRAINING AND PHYSICAL DEVELOPMENT.

IN a most comprehensive survey of the health of workers in the garment industries, Schereschewsky (*Public Health Bulletin*, 71) found that, while as a rule, the general health conditions of the workers was very poor, with the maximum amount of disease and defect, he was, nevertheless, able to note one exception to this rule in the persons of the workers of foreign birth who had undergone military training, even when many years ago. These were able to engage in the more arduous parts of this industry with the least amount of physical detriment. Their posture remained good, and the amount of defective conditions was at a minimum among them. In this same exception belonged the very few among these workers who engaged in physical exercise or in athletics.

It is to the effect of military training in part, and to the biologic effect of new blood instilled by Europeans, that Woodruff (*Medical Record*, April 27, 1912) ascribed the raising of the athletic standard of this country. On the other hand, the same criticism can be made of military training that can be made of athletics in general or of college athletics in particular (Friedman, *J. A. M. A.*, March 9, 1912), namely, that all three of them choose only the best, train these to the highest degree, and leave untrained those that would be the ones most benefited by such training.

In any competition, however, where physical training of a high degree is necessary, the first line or flower succumbs to the first shock, and the second or later line bodies must be drawn from the various grades of physical rejects who combine their physical inferiority with the lack of previous training; and because of the number of these having definite and uncompensated physical defects, the inferiority of the mass becomes greater.

Military or athletic training, to be of universal benefit, whether for immediate military purposes or for raising the physical standards of the citizenship, or for ultimate military purposes, must train every individual, but espe-

cially the weak and the defective. The training of the latter shall, however, be aimed particularly at bringing out and using the strong qualities. The army of otherwise rejects would be trained to be an army of specialists. Besides, in drawing on all physiques and all types there would always be under training a representative average. Later lines would no longer represent only the rejects but would again be a representative average, with the added advantage that material that would otherwise not be used at all is now utilized in special endeavors in which they have special abilities. It seems that Nature always compensates other faculties by enlarging them for the ones that are defective. In modern times it is not pure brute strength which is alone required, and there are parts of a military or athletic organization where defectives of even high degrees can be utilized in some special fields. An individual who has found a place for himself in civil life despite his physical defects can find a place in these organizations. The principle of the conservation of energy holds everywhere.

Moreover, a recruiting medical officer or a college physical director must not be merely a separator of the good material from the bad, but his main field must be—and here a greater degree of discriminatory diagnostic ability will be necessary—to find out the nature of a defect, its extent, and the extent to which it will hamper an individual; and, further, to find out whether, and to what extent, such an individual excels in other capacities in order that he may be assigned a place in an appropriate field. Many otherwise helpless individuals would thus be assisted to find themselves physically and later, perhaps, industrially. Many instances of physical weakness are due to lack of exercise, sedentary occupations and faulty postures, and in these particularly would military training be of value. At present there is usually a highly trained military or athletic body of small minor proportions, and very much nullified by the major portion of untrained athletic or military bodies.

As a matter of fact, it is probably true that a modified universal military training, so arranged as not to interfere with the education of young men for their future occupations in civil life, would be of advantage to this country, not only from the economic standpoint of physical and industrial efficiency, but psychologically as a corrective of the lawlessness and ill-discipline which are among the gravest defects of American civilization.

EPIDEMIC ACIDOSIS IN CHILDREN.

THE recent occurrence in Belmont of two sudden deaths of children from acute epidemic acidosis recalls the grave importance of this unfortunately uncommon affection and raises the hope that in this instance a more widespread epidemic of the condition may not follow these two apparently sporadic cases. In the issue of the JOURNAL for May 20, 1915 (Vol. clxxii, page 747) we published an article by Dr. Arthur A. Howard of Boston on acidosis in children and in our editorial comment upon this article in the same issue we referred particularly to the valuable work of Dr. Carleton R. Metcalf of Concord, N. H., on the epidemic form of the disease. Dr. Metcalf's paper, which was published in the issue of the *American Journal of Diseases of Children* for January, 1915, was based on a study of one hundred consecutive cases occurring in the vicinity of Concord within a few months. At the present time, the attention of physicians is particularly referred to these two articles and to others noted in the editorial above mentioned. Familiarity of practitioners with the clinical picture presented by this somewhat rare disease is the more desirable at this time, since it may lead to the earlier recognition and prompt treatment of other cases that may arise in this vicinity, thereby, perhaps, saving lives which might otherwise be lost, and possibly leading to the observation of new phenomena concerning the disease which may be of value in its further study and explanation.

MEDICAL NOTES.

STANDARD DIETS FOR HEALTH DEPARTMENT HOSPITALS.—In order to establish standard dietary methods in the hospital service of the New York Department of Health, the Director of the Bureau of Hospitals sometime ago appointed a menu committee composed of the resident physicians, supervising nurses, matrons, and the dietitian of the Department's hospitals, directing the committee to prepare standard menus, a basic dietary table, and rules and regulations for the guidance of the employees in the kitchens and dining rooms. At the time of its appointment, this committee was instructed to make certain that the quality of the foods in the new menus would not be below that of the food in use at that time.

The new dietary methods were introduced in January, 1915, and have given complete satis-

faction. Not only has the quality of the food been above criticism, but as shown by the report for the first three quarters of the year 1915, a saving has been effected amounting to nearly \$10,000 in nine months in the contagious disease hospitals alone. In comparison with 1914, this represents a reduction of 32/3 cents in the average per capita food cost.

This saving has been accomplished in three ways: *First*, by actually diminishing the amount of high-priced food (meat) in the various dietaries, and substituting therefor other food-stuffs which were equally nutritious and agreeable. This substitution, of course, was made without the knowledge of the employees and patients. *Second*, by eliminating waste in the preparation of the food, an elimination made possible by the use of standard menus. *Third*, giving the employees the kind of food that they wanted, thus reducing plate waste.

These statements are from the weekly bulletin of the New York Department of Health for December 11, 1915.

NEW COURSES OF INSTRUCTION TO FOOD INSPECTORS.—In order to perfect inspectors in the details of the various branches of their work, Mr. Lucius P. Brown, Director of the New York Health Department's Bureau of Food and Drugs, has organized a course of lectures, conferences and demonstrations dealing with the various aspects of pure food work. These lectures are in the nature of a post-graduate course, and each detail of the work will be presented by experts selected from the inspecting force.

The plan of the course will be to have a general lecture first, followed by demonstrations to squads of not more than five in the field. It is expected that these demonstrations will last about a week in each subject.

Supervisor Inspector Geertsema, who is now delivering the course of lectures on meats, gave his first demonstration at Health Department headquarters on Friday. Inspector Huntington, in charge at Fulton Market, will begin next week and will handle the course in fish. Subsequently, Inspector Holborn will take up oysters, and other experts will be detailed to cover the other subjects.

PREVALENCE OF MALARIA, MENINGITIS, PELLAGRA, POLIOMYELITIS, SMALLPOX AND TYPHOID FEVER.—The weekly report of the United States Public Health Service for November 26 states that during the month of September, 1915, there were in Arkansas 1977 cases of malaria and 104 of pellagra. During October there were in Massachusetts 19 cases of cerebrospinal meningitis, 28 of poliomyelitis and 402 of typhoid fever. During the same period there were 83 cases of poliomyelitis in Ohio, 35 in Michigan, and 28 in Minnesota. There were 96 cases of smallpox in Ohio and 602 of typhoid. There were 488 cases of typhoid in Maryland.

TYPHUS FEVER IN MEXICO.—Report from Mexico City on November 29, by way of Laredo, Texas, states that typhus fever has been extensively prevalent in the former city for the past two months. It is estimated that there are at present 11,000 cases in its immediate vicinity and that there is an average of 120 deaths a day from this disease.

NEW YORK DEATH RATE.—There were 1282 deaths in New York City during the past week as compared with 1385 during the corresponding week of last year, the respective rates being 12.52 and 12.94. This difference of 1.42 points means a decrease of 158 deaths or a saving of 158 lives. During the first forty-nine weeks of 1915 the death rate was 13.52 as compared with 13.69 for the corresponding period of 1914.

CORNELL UNIVERSITY MEDICAL COLLEGE.—In the issue of *Science* for December 3 is published the following account of the recently reorganized surgical service of the Cornell University Medical College at the Bellevue Hospital:

"At the head of the service there is now one 'visiting surgeon in charge' with a continuous service. He has general supervision over the entire work and is responsible only to the college and the hospital for its proper performance. There are two visiting surgeons who also have a continuous service limited to some special subdivision of general surgery. They are thus relieved of all routine work in order to devote their time to the particular work with which they are occupied. Under the visiting surgeon in charge are two associate visiting surgeons. These men are on the full-time salaried basis, and each has the care of one-half of the service. They have as assistants four juniors who are also surgeons to the out-patient department. The organization now also includes a laboratory of surgical pathology and a laboratory of experimental surgery, each under a full-time salaried man. These laboratories are available to all members of the staff, who there have the privilege of working on their individual problems. The entire staff has been appointed to positions in the department of surgery in the Medical College, and all students take a portion of their surgical ward work under this organization. The essential changes from the former system consist in having one head, continuous service, full-time salaried surgeons and laboratories under the immediate jurisdiction of the surgical service. Following is the staff as at present constituted: John A. Hartwell, M.D., assistant professor of surgery, visiting surgeon in charge; George Woolsey, M.D., professor of clinical surgery, visiting surgeon; John Rogers, M.D., professor of clinical surgery, visiting surgeon; Kenneth Bulkley, M.D., instructor in clinical surgery, associate surgeon; James Worcester, M.D., instructor in clinical surgery, associate surgeon; Fenwick Beekman, M.D., instructor in operative surgery, junior surgeon;

Benjamin Vance, M.D., instructor in pathology, surgical pathologist; J. W. McMeans, M.D., assistant in surgery, assistant in experimental surgery."

COLUMBIA UNIVERSITY PRE-MEDICAL COURSE AT THE LONG ISLAND COLLEGE HOSPITAL.—Beginning in September, 1916, Columbia University will give university courses in chemistry, biology, physics, French, German and English, at the Long Island College Hospital in Brooklyn, covering one year of college work.

STATE SURVEYS FOR STATISTICS OF INSANE.—The National Committee for Mental Hygiene, New York City, has a number of interesting plans on foot, involving surveys of different states as to the public and private provision for feeble-minded, epileptics, insane and allied defects. They have issued a map giving state surveys completed, under way and to be undertaken next. State surveys appear as completed for Pennsylvania, South Carolina and Wisconsin. State surveys under way are those for Arkansas, Missouri, Texas and Florida. State surveys to be undertaken next are Maine, Rhode Island, Connecticut, New Jersey, North Carolina, Georgia, Tennessee, Indiana, Illinois, Iowa, Kansas, Oklahoma, Washington, Oregon and California.

Of course a number of states in which the history of provision for the insane and allied defectives is longer and more complex are not regarded as requiring surveys at the present time. Massachusetts, New York and Michigan may be classed in this group of states not requiring mental hygiene surveys.

TRACHOMA IN THE UNITED STATES.—The outbreak of trachoma among school children in Jerome, Arizona, has been reported by the National Committee for the Prevention of Blindness, whose assistance has been requested in preventing the spread of the disease. Jerome is a mining town of three thousand inhabitants and is contiguous to a number of Indian reservations. According to the figures of the United States Indian Service, about 24% of the Indians in Arizona are afflicted with trachoma. It is supposed that sufferers from the disease, in coming to Jerome for supplies, spread the infection. In Douglass, Arizona, systematic inspection and treatment of school children afflicted with trachoma, is wiping out the disease. Whereas 78 cases were discovered there last year and placed under observation and treatment, only four new cases were discovered this year. In California the State Board of Health has taken precautionary measures to prevent the spread of trachoma by prohibiting children suffering from the disease from attending school.

In a recent bulletin of the State Board of Health of Kentucky, devoted to "Prevention of Trachoma," we find the statement made a number of times that trachoma not only exists in the

eastern section of the state, but is also found to considerable extent in the Blue Grass country and through the south and west. Dr. John McMullen, U. S. Public Health Service, and Dr. A. T. McCormack, who have been making a survey of conditions in Kentucky, have recently been making examinations of the eyes of school children in a number of the hitherto unvisited cities. Their investigations have shown that there is scarcely a community where trachoma may not be found. For instance, in Henderson, 81 pupils were excluded from the schools on account of trachoma; in Hopkinsville, 46 cases were found among 500 children examined; in Paducah, 97 cases were found out of 728 pupils examined. In fact, in practically every school visited, the number of children found with this disease, either well developed or in an incipient stage, was far beyond expectations.

A report from Oklahoma states that Mr. Charles Page, a millionaire oil operator of that state, will establish at Sand Springs, a semi-charitable eye hospital and sanitarium at a cost of \$200,000. The institution will consist of several buildings covering about eighty acres. There will be distinct units for whites, Indians and negroes. Trachoma, with which disease, the report states, about 75 per cent. of the Indians of Oklahoma are afflicted will receive special attention. The institution will be under the management of Dr. Daniel W. and Dr. Peter C. White, who for years were the Government trachoma experts, working among the Indians of Oklahoma.

A hospital for the treatment of trachoma has been established at Welch, McDowell County, West Virginia, by the West Virginia Health Council, with the coöperation of the United States Public Health Service. The health authorities decided to establish the hospital at Welch, as it was found that trachoma was widely prevalent in that county, but cases from any part of the state will be treated there.

EUROPEAN WAR NOTES.

ASIATIC CHOLERA IN AUSTRIA-HUNGARY.—The weekly bulletin of the United States Public Health Service for December 3, 1915, states that during the week ended August 21, 1915, there were in Bosnia-Herzegovina seven cases of Asiatic cholera. During the fortnight ended August 28 there were in Austria 8414 cases and 4996 deaths of this disease, the majority being among the civil population. During the week ended September 27, there were nine cases and four deaths of cholera in Croatia-Slavonia.

ARRIVAL OF HARVARD SURGICAL UNIT.—Report from Mr. Herbert H. White, manager of the Third Harvard Surgical Expeditionary Unit, announces the arrival of this unit at Falmouth, England, on Saturday, December 4. "The unit was met by Col. Sir Alan Perry (commanding

officer of the 22d General Hospital, where the first unit gave its service) at Falmouth, Eng., and by ex-Ambassador Robert Bacon in London; has been entertained at Oxford University by Sir William Osler (who was largely instrumental in the origination of the project of hospital units from American universities giving service with the sufferers of the armies in Europe); is to have luncheon with the London Harvard Club before moving forward to the hospital December 8 or 9."

VICTORIA CROSS AWARDED TO A PHYSICIAN.—In the issue of the *London Gazette* for November 18 is announced the award of the Victoria Cross to First Lieutenant George Allan Maling, M.B., R.A.M.C., "for most conspicuous bravery and devotion to duty during the heavy fighting near Fauquissart on Sept. 25, 1915." In the dispatches Dr. Maling's conduct is described in the following terms: "Lieutenant Maling worked incessantly with untiring energy from 6.15 a.m. on the 25th till 8 a.m. on the 26th, collecting and treating in the open under heavy shell fire more than 300 men. At about 11 a.m. on the 25th he was flung down and temporarily stunned by the bursting of a large high-explosive shell which wounded his only assistant and killed several of his patients. A second shell soon after covered him and his instruments with debris, but his high courage and zeal never failed him, and he continued his gallant work single-handed."

Dr. Maling is the son of a physician and was born at Darlington, England, in 1888. He was educated at Oxford and received his medical training at St. Thomas's Hospital, London. He was commissioned Lieutenant in the Royal Army Medical Corps on January 18, 1915, and went to France in June with the 12th Rifle Brigade. This is the first instance in which the Victoria Cross has been awarded to a physician during the present war.

WAR RELIEF FUNDS.—On Dec. 11 the totals of the principal New England relief funds for the European War reached the following amounts:

Jewish Fund.....	\$70326.65
New Belgian Fund.....	77,716.06
Serbian Fund.....	56,038.86
French Fund.....	29,407.39
Armenian Fund.....	24,683.38
Surgical Dressings Fund	14,239.00
Italian Fund.....	13,279.69
La Fayette Fund.....	13,088.99

BOSTON AND NEW ENGLAND.

THE WEEK'S DEATH-RATE IN BOSTON.—During the week ending December 11 there were 249 deaths reported, with a rate of 17.84 per 1000 population as compared with 216 and a rate of 15.65 for the corresponding week of last year.

The principal increases were pneumonia 43 against 23 last year, and heart disease 45 against 30 last year.

There were 41 deaths under 1 year as compared with 23 last year, and 90 deaths over 60 years of age against 75 last year.

Total deaths reported in 49 weeks from Jan. 2 to Dec. 11 were 11,113 against 11,080 for the corresponding period in 1914.

Deaths under 1 year reported in the same period were 1884 against 1860 for the corresponding period in 1914.

During the week the number of cases of principal reportable diseases were: diphtheria 76, scarlet fever 57, typhoid fever 1, measles 49, whooping cough 93, and pulmonary tuberculosis 57.

Included in the above were the following cases of non-residents: diphtheria 9, scarlet fever 10, measles 1 and tuberculosis 6.

Total deaths from these diseases were: diphtheria 1, measles 1, whooping cough 1 and tuberculosis 20, in which is included the following death of a non-resident diphtheria 1.

YOUTHFUL INSANITY.—The November bulletin of the Massachusetts State Board of Insanity reports the commitment of a little girl, aged nine years to the Medfield State Hospital. She was born in New York of Italian parentage, and had been admitted to the Psychopathic Hospital on July 22 and discharged August 20, 1915. Her mother being unable to control her, she was again admitted on September 4, and on September 9 was committed with a diagnosis of juvenile psychosis, of the manic-depressive type. The Board has since transferred the child from the Medfield State Hospital to the Massachusetts School for the Feeble-minded at Waverley.

Probably the youngest person committed to a state hospital as insane was a child of four years who was committed to the Taunton State Hospital in 1899. The September bulletin recorded the commitment of probably the oldest person on record, being one hundred years and two months old.

GIFT TO HARVARD MEDICAL SCHOOL.—A gift of \$75,000 has been announced to the Harvard Medical School. This is the balance of the bequest of Morrill Wyman, who established the Morrill Wyman Medical Research Fund, the income of which is to be applied in promoting investigation concerning the origin, results, prevention and treatment of disease.

FREE HOSPITAL FOR WOMEN.—The recently published report of the Brookline Free Hospital for Women shows an increase for the year ending October 1, 1915, in the number of patients treated. The total number of patients operated on was 716. The number of consultations given

in the out-patient department were 6943, 1748 being new patients; 858 patients were referred to the hospital for further treatment.

ENDOWMENTS FOR SOCIAL SERVICE DEPARTMENT.—Announcement was made at the tenth anniversary session of the Social Service Department of the Massachusetts General Hospital that endowments to the amount of \$40,000 have been given to the Department. Mrs. Shepard Brooks has given \$15,000 and Charles Mosely of Newburyport, \$25,000.

INFANTS' HOSPITAL.—The Infants' Hospital is calling attention to its need of funds to carry on its work among sick and needy infants. The hospital can care for 800 more babies annually than it now has funds to support. To do this would require \$30,000 more a year. The hospital receives only \$6594 from invested funds and a small income from private patients and must depend upon gifts for any increase in its work. Last year it cared for 650 patients. With the exception of the summer accommodations of the Floating Hospital the facilities of this community to provide adequate care for its infants and to supply opportunities for research work are meager indeed, and a competent endowment of the Infants' Hospital is not only to be desired but is urgently necessary. Contributions may be sent to Mr. Nelson S. Bartlett, Treasurer, care of the Old Colony Trust Company, 17 Court Street, Boston.

PETER BENT BRIGHAM HOSPITAL.—The graduating exercises of the school for nursing at the Peter Bent Brigham Hospital, Boston, are to be held in the hospital at 8 p.m. on Friday, December 17 and will be followed by a reception until 11 p.m.

Miscellany.

MEMORIAL RESOLUTIONS FOR WILLIAM NOYES, M.D.*

WILLIAM NOYES died at his home in Jamaica Plain, October 20, 1915. The end came suddenly after an illness of many months, the gravity of which he fully realized.

He was the son of William and Martha Jane (Bailey) Noyes and was born in Boston, November 6, 1857. He was graduated from Harvard College with the class of 1881 and from the Harvard Medical School in 1885. While in the school he was a clinical clerk in the Danvers State Hospital for four months, and after graduation accepted a fellowship in psychology at the Johns Hopkins University. He was for a

* Adopted at a meeting of the Boston Society of Psychiatry and Neurology.

short time resident physician of the Baltimore City Lunatic Hospital, and in December, 1885, was appointed second assistant physician of Bloomingdale Hospital, New York.

He early became interested in the field of research in psychiatry, and in February, 1889, accepted an invitation to organize a psychological laboratory at the McLean Hospital, supplementing his previous preparation for the work by nine months of study in Vienna and Berlin.

It was pioneer work, difficult and too often yielding negative results, which he modestly declined to publish, so that of much that he did there is no record. Among other studies, he made investigations on the reflexes and published a part of his work in an important paper "On Certain Peculiarities of the Knee-Jerk in Sleep in a Case of Terminal Dementia." He made frequent contributions of critical reviews, chiefly to the *American Journal of Psychology*.

In February, 1892, he accepted the position of assistant physician of the Massachusetts Hospital for Dipsonmatics and Inebriates, where he remained until April, 1896, when he was elected superintendent of the men's department of the Boston State Hospital. He was made superintendent of both departments of the hospital in May, 1905, which position he held until January, 1910, when he resigned to engage in private practice.

There can be no doubt that the change to the clinical and executive field was due to the lack of appreciation in that day of the money value of purely scientific work, which, unfortunately, still obtains, though in a less degree.

He was connected with the Boston State Hospital for nearly fourteen years and gave it faithful service. It was a transition period, the many difficulties and anxieties of which no doubt contributed materially to the onset and progress of his illness.

After his retirement from hospital life he made a careful investigation and census of the feeble-minded outside of institutions in Massachusetts, at the request of the State Board of Insanity, and rendered to the Board a most interesting and valuable report, which, unfortunately, has not been published.

For many years he was a clinical instructor in mental diseases in the Harvard Medical School. He was a member of the Massachusetts Medical Society, the American Neurological Association, the American Medico-Psychological Association and of the Boston Society of Psychiatry, of which he was the secretary at the time of his death.

He was an able man, of good judgment, but it was not easy for him to make decisions in important matters, and he did his work with many anxieties, contrary to the impression he gave those with whom he was not intimate. He was modest, sensitive, a man of warm friendships, domestic in his tastes, a loving husband and father.

Resolved, That the Boston Society of Psy-

chiatry and Neurology place on record its appreciation of the character and attainments of Dr. Noyes and the deep sense of the loss it has sustained in his death.

Resolved, That a copy of these resolutions be sent to Mrs. Noyes and his sons, be spread on the records of the Society, and printed in the BOSTON MEDICAL AND SURGICAL JOURNAL.

CHARLES G. DEWEY, M.D.,

GEORGE T. TUTTLE, M.D.

Correspondence.

PARIS LETTER.

THE POWER OF ADAPTATION OF THE HUMAN MIND.
(From Our Special Correspondent.)

PARIS, NOV. 13, 1915.

Mr. Editor: Psychology has somewhere been defined as the endeavor on the part of the mind to find out its own little game. Now, although this particular branch of study has never presented any special attraction to me personally, such a thing as going through life without giving the matter any thought at all is of course inconceivable, and I may frankly admit that there is one way in which the Ego reacts that still arouses in me unbounded wonderment as each new instance presents itself, in spite of a stretch of experience that is now beginning to be somewhat extended: the amazing facility with which a man accepts an altogether new, unexpected (not to say revolutionary, and, in many cases, extremely painful) change in his conditions of life.

During my travels throughout the breadth and length of Europe I have visited castles and strongholds without number. The greater part of these that go back a certain number of centuries contain prisons, dungeons, blackholes, oubliettes, etc., in which it was the custom in those merciless days to imprison enemies for periods of a few weeks or months, up to decades of years, in some cases in total darkness, in others under such circumstances that the wretched inmate could not by any possibility assume the erect position, and in still others under the most frightful conditions of dampness, draughts, vermin and fetters. In practically all these places of confinement there was nothing but stone and earth; some were cut out of the actual rock. The food was usually bread and water, and the arrangements for the excreta of the body non-existent,—yet in cases without number not only men but women and children were taken from surroundings of luxury and thrown at a moment's notice into such dungeons, where they were held for years and years, to come out finally not only apparently none the worse physically but even in a fairly composed state of mental equilibrium! This is one of the most striking instances of the adaptability of the human mind that I have met, and it is all the more remarkable in that, in the generality of cases, the said mind had been, through the entire period of incarceration, not only deprived of all intellectual pabulum, but even of the sound of the human voice. The dungeons at Loches, in Touraine, are one of the most amazing illustrations of what an ingenious mind can devise in the way of prisons. Those at Coucy are likewise fairly remarkable.

The following is also a rather striking example of an utter upheaval in a person's life and prospects, and one which medical men are unfortunately called upon to witness only too often. It is that of the prosperous man between fifty and sixty, who has made his way in life, has a charming family, and has left the city perhaps and centered his interests on a country house or farm; to all external appearances his situation seems one that anyone might envy, and his con-

dition of health points to long life and happiness. Yet he has for some time back been having trouble with his intestinal functions; he then notices that his weight is falling off; finally he has a hemorrhage from the bowel, and the proctoscope reveals an epithelioma fifteen or twenty centimetres up. Exploratory laparotomy then shows dissemination throughout the entire peritoneum, with possible secondary deposits in the liver, and we know that our prosperous and healthy man has not three months more before him. Is there one of us that has not been awed by the apparent ease with which such a man accepts his fate? It is something positively incredible.

A third instance of this astounding pliability of the human mind was brought to my notice recently in the following manner. My bell rang the other afternoon and there was ushered in a tall, slim youth in a rather-the-worse-for-wear khaki uniform, whom, after a moment's uncertainty and surprise, I recognized as a young Englishman of my acquaintance, one of those clean, well-set-up, pink and white lads of which Great Britain alone possesses the secret, the sort that we generally associate with flannels, velvet tennis-lawns, long summer evenings, and simple, well-groomed girls with soft, low voices and beautiful white teeth. But my young paragon was a weedy-looking customer now, and no mistake; he looked very much as though he had had a personal encounter with the neighbor's bull, and had by the same agency been rapidly transferred through the air to the adjoining lot. His juvenile beard and hair were sadly unkempt, and his uniform and heavy shoes, though cleaned, had a curious grayish-white hue that revealed the clay of the Champagne trenches.

He was eighteen or nineteen; had enlisted as a chauffeur, as he was very keen on motoring; and had been told off on one of the ambulance sections back of a French corps d'armée. And Fate had pitchedforked this innocent stripling, whose previous view of life, as I said, had not extended beyond pretty girls, tea-parties, and the lovely landscape of a south-western county,—into what do you suppose? all the terrible fighting during the French attack in Champagne of September 25th and the days following! He had now been sent to Paris to take over two new ambulance-cars with all the latest improvements; and as he and his companion had been a little "chesty" about showing their papers to the military police at the railroad station the previous evening, the two of them had just spent the night and part of the day at the military jail! But do you suppose that any of these experiences, rather new and startling it would seem to a callow youth of eighteen fresh from his mother's and sisters' skirts, upset the equanimity of this scion of Albion? Not the least bit. I kept him to dinner, and he told me the entire tale in as simple and natural a manner as though he had been describing the occurrences of fair-day at the nearest county-town. I verily believe he would have warmed up more if he had been speaking of the encounter of his favorite eleven with a rival team! At any rate, here is, in a few brief lines, what this refreshing innocent had just passed through.

After serving a while in the west of the line, his section of cars was ordered east of Rheims, and the men had just had time to get themselves installed when the big attack began. He and some of the others had set up housekeeping in a hole in the ground; it seems this is warmer than life under canvas, though the rats are a perfect plague and interfere with sleep. Their trick was to run from the end of the exit-communicating-trench back three kilometres across open country pitted with shellholes and without roads, to the first-aid station about on a level with the French artillery hidden away in the wood. The French front-trenches facing the enemy have entrance and exit trenches running backwards for a long way at right-angles, and the badly wounded men are brought along the exit-trenches by two bearers and a two-wheeled sort of barrow-stretcher. The exit is sheltered from fire by a bank, behind which is stationed

a surgeon for urgency first-aid,—bad hemorrhage, etc. while overhead can be heard the whiz of bullets p-r-r-t, p-r-r-t. The ambulance loads up at this point and then makes its way back as rapidly as circumstances allow, under fire all the time, and with the roar of the French guns *right in its face*, naturally the shells passing overhead! My young acquaintance had never been hit, though his car had. During the French attack this section of ambulances carried back nearly 6000 stretcher-cases, and for three days and nights the men neither lay down nor took off their clothes; they got something to eat as best they could, all cold, and slept an hour or two in the corner of their driving-seats when they could hold out no longer.

Well, you would have thought that this was hectic enough to stagger my pink and white boy; but what is more extraordinary still was the matter-of-fact way in which he described the appalling scenes of butchery he had been called on to witness. With these modern, high-explosive shells, which are practically the only sort used in trench warfare, the shrapnel being of very little service, men are simply blown to bits. A limb, two limbs disappear into thin air,—nothing left of them. If the soldier is not killed out right, he may die during removal along the exit trench, or during motor-transport back to the first aid post. The receiving surgeon then simply has him rolled out of the stretcher onto a pile of other similar cases, and the stretcher starts back on its return journey. At the three-kilometre station first-aid is rendered, and another service of motor-ambulances then takes the less serious cases on to rail head, or to a large emergency base-hospital with 1800 beds, familiarly known as the graveyard, as so few of the wounded admitted ever come out again. This hospital takes all the bad cases, head, chest and abdominal wounds, and shattered limbs that will not bear transportation. It seems that in the vicinity of this cheerful establishment there is a large pit, the size of a big dwelling room, entirely given up to the reception of amputated portions of human anatomy, arms, legs, etc. An orderly appears with a big basket, from which he dumps out a consignment of limbs, and then scatters some earth over them; shortly afterwards another orderly appears, goes through the same performance, and so on.

Now, my youth had been moving in this atmosphere for weeks, and you would have thought that the mere horror of the thing would have sufficed to turn his hair prematurely white; yet he told me all about it as quietly and naturally, and with as little emotion or use of superlatives, as though he had been talking about his father's stables or his mother's flower garden. Nor was there so much as a suspicion of "pose" about the affair; he was not affecting the indifferent, or playing a part, in the slightest degree. No. His mind had merely adapted itself to the circumstances so thoroughly that it was to him simply his day's work, his "little bit", to use the British term; this was his job, just as it otherwise might have been his job to start from his country-place each morning catch a train, and go in to work at a bank in the city, as so many other of his young acquaintances undoubtedly do. And he has now gone back to the front again as cheerful as a sandpiper, buoyed up by the hope of a week's leave at Christmas, when, as he remarked, he jolly-well intends to scuttle across the channel and show himself to the "Mater",—though I fancy there will be a pretty girl not far away that will have to be looked up, when he has paid his respects to the said Mater; he appeared to me to dwell rather more on this prospect of getting home than young men usually do when their mother alone is in question.

But could any more striking example of the marvellous adaptability of the human mind be imagined than the case of this youth? Men can stand a good deal, as we all know; but there are not so very many laymen who can view unmoved a mangled human body.

MEDICAL RELIEF IN BELGIUM.

(From Our Special Correspondent.)

OXFORD, Nov. 9, 1915.

Mr. Editor: At a meeting of the Central Committee for the Belgian Doctors' and Pharmacists' Relief Fund on October 21st a report was made by the committee of Belgians which has been distributing the Fund, namely the "Aide et Protection aux Médecins et Pharmaciens Belges Sinistrés." The report showed an increase in the number of medical men in Belgium who are receiving pensions from the Association.

It seems that the Belgian Committee has not been able to give assistance to the medical men of Belgium as freely as it would like. Many worthy requests for assistance were refused inasmuch as the committee was not empowered to do anything more than relieve the daily needs of their applicants. The English Committee, which has largely financed the scheme, has done so with the following provision:

"No moneys must be distributed except for the immediate pressing needs of the individual sufferers, and in no case for restarting them in their profession or private affairs."

Under these circumstances the Belgian Committee decided to sell some of the medical supplies sent to them by American doctors. The money thus obtained, they thought, would be well spent in helping those medical men in Belgium who were in need of special assistance but who were ruled out by the provision of the English committee. The Belgian Committee, therefore, approved the creation of a special fund of 25,000 francs. Out of this money advances were to be made for damaged premises and, as far as possible, assistance given for rebuilding practices.

It was decided that help should be given only in cases of the most urgent need in order that those, whose losses were comparatively small, might not deprive others, who had been entirely ruined, of indispensable assistance. Each distribution of money was to be made with the understanding that it should be paid back in better times.

In this report, Dr. Pêchère, the president, said in part:

"The committee invites you to endorse its action, being of the opinion that no other disposal of the money could better carry out the intention of our American confrères than that proposed by M. Coppez and the special commission—viz., the transforming into a reconstruction fund the product of a sale of drugs and medicaments which are still fairly easily obtainable, and of which the distribution would have been difficult and expensive. Assured beforehand of your consent, the special committee has undertaken again the examination of the dossiers, several of our confrères finding themselves in immediate need of benefiting under the scheme without delay."

Reports by M. Laruelle showed the conditions of some of the doctors in Belgium and the grounds upon which grants from both funds were made. Some of the cases cited are given below:

"Dr. C—, of D—, ruined like the other medical men of his city by the complete destruction of his house and its contents, and the almost total ruin of his clientèle, received in April last an allocation of 600 francs. A monthly allowance was granted of 700 francs for three months as from July."

Mme. M—, of E—, whose husband had joined the Belgian army after the destruction of his property and practice, is a chronic invalid. She has been received into a charitable institute. An allocation was made to her of 800 francs in May. A further grant of 700 francs was made in the month of September.

Dr. T—, of H—, 70 years of age, with two dependent children, has lost his practice. He received a monthly grant of 600 francs in June, July and August, and a further grant of 200 francs was made

for September. The same sum was granted Dr. D—, of B—, for September. He continues to practice in B—, but that village has been almost destroyed. He has received a grant of 400 francs in June."

Announcement was made that three more cases of instruments had been recently sent into Belgium through Mr. Hoover, the American who is at the head of the Commission for Relief of Belgium, and the secretary reported that former consignments of instruments had been gratefully acknowledged.

The financial statement of the English Committee shows that up to the date of the meeting about \$90,000 had been contributed to the fund.

DRUG TRADE WITH GERMANY.

On October 21st, Sir Edward Grey, in response to questions concerning the importation of drugs and other manufactured articles from Germany, said in part:

"What His Majesty's Government is to do is to give directions to His Majesty's ships that particular consignments are not to be captured and brought in for adjudication in a prize court. As regards goods ordered and delivered since March 1, 1915, such action has only been taken: (1) in the case of a few consignments of certain drugs unobtainable except from enemy territory, such as salvarsan and novocaine; (2) in case of certain natural products, e.g. sugar-beet seed, urgently required by important industries in other countries, and unobtainable except from enemy territory; and (3) in the case of machine knitting-needles, beet-sugar slicing knives, scientific or technical publications required by universities or educational establishments in a neutral country, and a few articles such as a stained glass window required by religious establishments to complete orders placed a long time ago with an enemy firm. It is difficult to form an estimate of the value of these articles, but I believe it would be certainly less than \$300,000 altogether. It should be added that these consignments have been allowed to pass either in response to urgent representations of certain neutral governments based sometimes on undeniable humanitarian grounds or to meet certain home demands."

On talking with one of the local druggists here I found that he is obtaining some drugs, for instance aspirin, from the enemy through Switzerland. I presume these drugs would not be included in Sir Edward Grey's statement. It is also possible to obtain from Germany or Austria any medical books which are not in print in England. A number of students in the university have received books direct from Vienna by ordering through the local Oxford booksellers. They are sent out by way of Holland, usually after a delay of several weeks.

Whether or not such practices are carried on generally throughout the country and with regard to books and drugs of other sorts, I do not know, but it seems quite possible.

Sincerely yours,

W. G. P.

EUTHANASIA IN WAR.

BOSTON, Nov. 27, 1915.

Mr. Editor: In the summer of 1864, we were making instructive studies of Peyer's glands, with the hope of giving more successful treatment to the many cases of chronic diarrhea in the Cumberland U. S. A. General Hospital at Nashville. A senseless alarm was sent to the War Department about the "cutting up" of deceased comrades and the receipt of an order forbade post mortem examinations. I was, therefore, unable, in the following case, to ascertain the deeper lesions, the condition of the optic commissure, etc.

The patient came to us, with about 700 other acute cases of gunshot injuries, on the night of the first day's fight at Nashville in December, 1864. Some of the men were brought in ambulances, but more in lay wagons without springs, a mile from the field, over frozen roads, deeply rutted by the wheels of batteries and supply trains of previous days. As acting executive officer, I was called to examine a man in one of the wards, who was persistently clamoring for euthanasia. When I reached him, sitting on a stool in the midst of a crowd, he asked me to stoop down, look at him and then listen to his request. I found that considerable parts of both optic cones had been shot away, including the arch of the nasal bones. There was now no arterial hemorrhage, no complaint of pain beyond a sense of soreness, no special constitutional disturbance. Pulse was notably small. Deformity of face was extraordinary. One eye ball had been carried off in the progress of the missile; the other rested on the cheek (half way down the face) held by its optic nerve. He began at once to argue his claim, in a slow, deliberate and low voice. He exhibited no hysterical haste to die, though it was evident that for him life and not death was "the king of terrors." He steadily maintained that life would be insupportable should he get about again. I listened as carefully as possible in the confusion of cries for attention of forty or more on the floor and the beds of the ward; doctors and nurses were embarrassed by their urgency. He was quiet. The clear working of the mind, the normal sequence of thought surprised me, looking down upon such ruin of structures in the very neighborhood of the anterior cerebral lobes. He politely paused for an answer. I cannot state verbatim what I said, but the gist of it was that none of us could revise the course of his case, nor be justified in hastening the approach of death by medical or surgical procedure. He died that night in coma.

The pith of all this is in two points: First, the gravity of the injury so close to the supposed region of cerebration, the anterior lobes, *without disturbing mentality*. Second, the cause of death. The word *coma* explains nothing; was it the over-topping hopelessness, an object repulsive to look at and even more so, to think of; the state of mind, producing excessive secretion in certain glands, thrown into the circulation as a toxin paralyzing innervation?

W. B. TRILL, M.D.,

Pittsburg, Pa.

RECENT DEATHS.

DR. FRANCIS C. MARTIN has died at his home, 27 Dudley Street, Roxbury, Mass. He was born Mar. 22, 1858, attended the Roxbury Latin School and was graduated from Harvard in 1879. Later he was graduated from the Medical School, and went to New York, where he continued his studies in one of the hospitals. After that he returned and took up his permanent practice in Roxbury.

Dr. Martin was a son of Dr. Henry A. Martin of Boston, a surgeon, and the first to introduce animal vaccine into this country. His mother was Frances Coffin Crosby, a daughter of Judge Crosby of Lowell, Mass. Dr. Martin was president of the New Hampshire Society of the Cincinnati, and a member of the Massachusetts Historical Society, the New Hampshire Historical Society, the Old Colony Club of Plymouth, Mass., and of the Harvard Club. He was a great lover of old books. Dr. Martin was a Fellow of The Massachusetts Medical Society from 1883 to October, 1914. He was an associate member of the Boston Medical Library, to which he had presented the collection of books on vaccination belonging to his father.

APPOINTMENTS.

HARVARD MEDICAL SCHOOL.—At the latest meeting of the Corporation of Harvard College, the following appointments were made in the Harvard Medical School: Dr. David Cheever, as associate in surgery; Dr. James L. Huntington, as fellow in obstetrics; Dr. Frederick C. Irving, as fellow in obstetrics; Dr. Foster S. Kellogg, as fellow in obstetrics; Dr. John B. Swift, as fellow in obstetrics; Dr. Samuel C. Harvey as Arthur Tracy Cabot fellow in charge of the laboratory of surgical research.

GRAFTON STATE HOSPITAL.—Dr. William A. MacIntyre has been appointed assistant physician to succeed Dr. George K. Butterfield, resigned.

BOSTON CITY HOSPITAL.—Dr. Edward B. Allen resigned from the Danvers State Hospital to accept an appointment on the staff of the Boston City Hospital.

NOTICES.

THE SOCIETY FOR THE ADVANCEMENT OF CLINICAL STUDY announces a continuation of its bureau of information relative to surgical and medical clinics held in New York City. A bulletin board is maintained for this purpose at the Academy of Medicine, 17 West 43rd Street, in charge of a competent attendant, who will be on duty from nine to twelve in the morning and two to six o'clock in the afternoon to answer inquiries. The special telephone number is 3375 Bryant. The clinics held at the various hospitals are posted on a special circular of information, which will be mailed to outsiders at 50 cents per week to cover postage, etc. The bulletin board maintained at the Academy also contains the daily clinics as well as those held at stated hours in various hospitals. The facilities thus offered afford to visiting physicians who are interested in observing special operations and operators or clinicians, an opportunity to obtain the desired end with the least trouble.

INFANTS' HOSPITAL, BOSTON.—A clinical meeting of the staff of the Infants' Hospital will be held at the Rotch Memorial Building, 55 Van Dyke Street, Friday, December 17, 1915, at 8.15 p.m.

SUBJECTS.

- I. Intravenous Injections in Infants.
- II. Diagnosis of Duodenal Catheter.
- III. Demonstration of Cases.

Members of the medical profession are cordially invited.

SYMMETRICAL SYNOVITIS IN HEREDITARY SYPHILIS.

By ABNER POST, M.D., BOSTON.

In the *Lancet* of February 27, 1886, Mr. H. H. Clutton, assistant surgeon at St. Thomas Hospital, published an article on "Symmetrical Synovitis of the Knee in Hereditary Syphilis" with a table of eleven cases. Of the eleven cases, Mr. Clutton furnished seven, Mr. Nettleship, of the eye department, furnished three, and Mr. Lawford furnished the eleventh.

The predominant features of the disease as reported in this article were the symmetry of the affection, the freedom from pain, the long duration of the symptoms, and the free mobility of the joints throughout the course of the disease.

There was in each case evidence of syphilitic heredity. The patient generally complained of stiffness in one knee which was then found full of fluid but not tense. On careful examination, the other knee was also found to contain fluid but not to the same extent as the one for which advice was sought, so that it is fair to assume that the knee to which attention was directed by the patient was affected some little time before the patient felt any inconvenience. It is referred to as an "insidious chronic synovitis." The swelling was accompanied by considerable thickening of the synovial membrane, but the marked feature was the increased quantity of

synovial fluid. The joints were never tense but gave a sensation of flaccid fluctuation. The bones were not enlarged. Sometimes nodes were found at a distance from the joint. There was no alteration in the knees for many months. Those that were treated by splints and rest in bed were as slow in getting well as those that had had no local treatment whatever. Of the eleven cases, nine had interstitial keratitis, and one had traces of an earlier attack. Five had Hutchinsonian teeth, four had nodes on the tibia, two were absolutely deaf.

A little study of Mr. Clutton's table shows that the interval which elapsed before the involvement of the second knee was sometimes so long that the first knee must have been considered by itself—and in other cases there was a considerable degree of tenderness in one or both knees. So that the variation in symptoms is sufficient to make the diagnosis sometimes obscure.

Although interstitial keratitis was present in ten of the eleven cases, symmetrical synovitis also occurs in cases in which interstitial keratitis is not present. In one personal case the diagnosis was nveitis: in another the patient was born blind—in still others there was no disease of the eyes present. Mr. Clutton believes this affection of the knees to be comparatively rare. Fournier mentioned Clutton's article in a foot note in his book on "Late Hereditary Syphilis" which was published in 1886, the same year as Clutton's article, and said that he could not doubt the accuracy of Mr. Clutton's observation though he had never seen identical cases.

A careful study of syphilitic children shows the symptom to be comparatively frequent. The fact that the joints are seldom fully distended,

that they are painless and interfere but little with locomotion explains their infrequent recognition. These joints have been compared to interstitial keratitis which is usually symmetrical but may be single or the two sides affected with so long an interval that the first case is single so far as diagnosis and treatment are concerned.

An example of Clutton's which occurred in a little girl who had also interstitial keratitis, Hutchinsonian teeth and chorea.

The same condition evidently occurs in synovitis of the knee. There was an interval of twelve months between the two knees in Mr. Clutton's eleventh case.

These knees are seldom painful but they sometimes make locomotion awkward. Patients trip easily. Sometimes the joints become somewhat flexed, and walking is more awkward and even difficult. The fluid is slowly absorbed but it is usually quickly diminished, sufficiently to relieve symptoms.

The fluid is thick and the capsule seems thickened, but the joint surfaces are not injured, so

that moderate exercise is not injurious. The thickened capsule and its contents show often a sufficient x-ray shadow to define the shape of the synovial cavity. The radiogram often shows changes in the tibia but none in the joint itself.

The recovery is usually perfect, but not always. One case to my knowledge recovered with slight flexion, which was never fully corrected, but the patient walks and has no disability beyond that incident to imperfect extension.

If we consider Mr. Clutton's knees as a type, it must be recognised that knees occur which are not true to type. A little girl in the orthopedic department of the Massachusetts General Hospital was admitted with knees which contained very little fluid and in which flexion was the most prominent symptom. There were no other

These two radiograms show the femora and one tibia from a case of symmetrical synovitis of the knees at the Children's Hospital.

signs which could be attributed to syphilis and the Wassermann report was negative. The x-ray of the knee joints showed no sign of disease in bone or cartilage but the tibiae showed a thickened cortex which was believed to be syphilitic. Within a short time, while she was still in the hospital, she developed an interstitial keratitis and a family history was obtained which was strongly suggestive of syphilis. The knees, and also the eye recovered under anti-syphilitic treatment. There is reason to suspect that joints of this class have been operated on as tubercular.

Symmetrical synovitis occurs in other joints. Mr. Clutton's eleventh case had a history of a swelling of both ankles at the commencement.

Taylor, in his chapter on dactylitis, says: "In some cases an effusion into the joint-cavity takes place slowly and without pain." A boy of ten with intermittent haemoglobinuria has symmetrical synovitis of both wrists and also elbows. His knees are quite distended with fluid. He was also a patient at the eye and ear infirmary for interstitial keratitis.

A young lady was referred to me recently with a question as to the character of the swelling of her knee. She is thirty-one years old, has had trouble with her knees ever since she was thirteen. Both knees are quite full. They vary in fullness from time to time; when they are tense they are quite painful and interfere with locomotion. She wears a bandage about them which gives her a sense of support. Her ankles are both distended with fluid and she always wears high shoes for the same reason that she wears the bandages about her knees. She has had no other signs that can be traced. Her parentage is unknown. Blood for Wassermann is negative. Her knees correspond exactly to Mr. Clutton's description. There has not yet been opportunity to learn the effect of treatment.

Local treatment of the knees seems to be unnecessary and in many cases actually harmful by confining the child when it needs fresh air and exercise. Treatment for the constitutional condition is, however, necessary. Mild mercurials often act very well but sometimes the iodides do better. Salvarsan may be used as an adjuvant, often with benefit, but a sudden absorption of the effusion is hardly to be expected. In general, treatment acts slowly. The effusion is absorbed sufficiently to allow free use of the legs but it can still be recognized for many weeks or even months after treatment has been instituted. Some cases which have not been recognized and treated hitherto as syphilis often respond very quickly.

Symmetrical synovitis of the knees has occurred so often in conjunction with interstitial keratitis and Hutchinsonian teeth that such a triad may be considered as valuable as Mr. Hutchinson's triad of interstitial keratitis, Hutchinsonian teeth and deafness.

SOME MODERN IDEAS ABOUT ANAESTHESIA.*

BY FRANK L. RICHARDSON, M.D., BOSTON.

THE duties of the anaesthetist have not been strictly defined. To my mind, the anaesthetist is to look after the welfare of the patient during the course of the anaesthesia, and to offer suggestions as to preliminary and post-operative treatment that concerns the anaesthesia. If this definition is roughly accurate it includes a number of duties besides the actual administration of the anaesthetic.

Not many years ago, it was enough if the anaesthetist got his patient off the table alive, no matter what discomfort the patients had before the actual business of operating, or what happened to them afterwards. Happily for all concerned, those days have passed in all enlightened communities. Not only is the surgeon critical, but the laity, at least in this community, expect certain refinements which not only add to the comfort and safety of the patient, but reflexly add to the reputation of the surgeon. A patient who has had one unfortunate experience will not be very likely to seek more surgical assistance unless he is actually driven to it—in fact he may influence others from seeking assistance by his tales of suffering. Please do not think that I believe that all suffering can be prevented by the anaesthetist, but I do feel sure that by proper coöperation between the surgeon and the anaesthetist a considerable amount of suffering can be avoided.

Let us begin with the preparation of the patient. The preparation depends to a certain extent on the field of operation, yet there are certain things done as a routine, such as the cleaning out of the intestines, and having the stomach empty.

It is the custom with some operators to give castor oil the night before the operation and an enema the morning of the operation. I believe that this is a most pernicious custom. While castor oil will certainly clean out the intestinal tract, it leaves a very unpleasant condition. Castor oil is an intestinal irritant and as a result of its use after the violent evacuation, peristaltic movements cease for a varying length of time. If the operation has been on the abdomen this period of intestinal stasis facilitates the accumulation of gas with results that are always painful and sometimes dangerous. Isn't it more rational to give a saline cathartic or Russian oil, followed by a cleansing enema, than to use castor oil? Catharsis should never be too active before an operation because of the debilitating effect, and I believe that it is time well spent to take two days in preparation in cases of chronic constipation or in cases where the intestinal contents must be completely evacuated.

*Read before the Chirurgical Society of Boston.

Another matter to be considered is the question of food. Here I realize that I am treading on dangerous ground and that no hard and fast rules can be laid down, but there are certain fundamental principals that should be considered.

Where either ether or chloroform is to be the anaesthetic selected, we should try to have the food contain as large an amount of carbohydrates and sugars as possible because it is well known that ether has a tendency to produce a condition of acidosis in patients not having a reserve supply of glycogen in the liver. It is also stated that the degenerative processes in the liver caused by chloroform anaesthesia are largely prevented if the liver has a sufficient supply of glycogen. Particular attention should be paid to this factor in children and debilitated patients. Starvation is above all things the condition that should be prevented, for where there has been a prolonged fasting the glycogen of the liver is rapidly used up. Diabetics form a special group, and I feel strongly that no diabetic should be operated on except in the gravest emergency without a preliminary course of dietetic treatment given by a competent medical man. While it is true that we get away with many operations on diabetics under ether, we are sometimes surprised and alarmed at the symptoms following comparatively trivial operations in other cases.

Around Boston, until within a very short time, we have hardly considered any other anaesthetic than ether. There are several reasons for this. Of all the general anaesthetics, except nitrous oxide, ether is the safest in the hands of the unskilled or moderately skilled. We have, too, a pride in the part Boston has played in the introduction of ether and this is one of the principal factors that has led to its traditional use here. Ether is not the only anaesthetic to be considered even if it is the safest in the majority of cases. Nitrous oxide, nitrous oxide and oxygen, chloroform, etc., must at least be considered, and in selected cases one of these is sometimes safer than ether.

I should like just to mention a few indications for the use of some other anaesthetic than ether. No case of tuberculosis of the lungs should be given ether without consideration of some other anaesthetic. The danger is in direct proportion to the activity of the process and the general condition of the patient. I have quite recently seen two cases of prolonged ether anaesthesia in which the administration of ether lighted up an old and unsuspected tubercular process. Fortunately in these cases the process quickly quieted down, but that was merely an accident. In tuberculosis of recent origin and especially in active tuberculosis, the patient may recover from the operation only to die from tuberculosis, and the anaesthetist, while he escaped censure, may have been responsible for the unfortunate outcome. Bronchitis is another condition in which one should consider some other anaesthetic.

Since the substitution of novocaine for cocaine in local anaesthesia we have been doing more and more operating with this form of anaesthesia. It has great advantages in many cases. In deciding between local anaesthesia and general anaesthesia there are a number of questions to be considered. Among these are duration of the operation, site of the operation, sepsis, the temperament and general condition of the patient. Local anaesthesia does one thing that must never be overlooked—it does away with the mental and physical discomfort of taking a general anaesthetic. It is true that this discomfort, thanks to more refined methods of giving general anaesthetics, is now much reduced, so that many patients have no physical discomfort and the period of mental discomfort is greatly shortened, yet to some people taking an anaesthetic rather than the operation is the thing to be dreaded. On the other hand, there are many people whose temperament contraindicates the use of local anaesthesia. They do not wish to be present at their own operation. The proper use of morphine and scopolamine will in many cases do away with this objection, and I wish to urge the more general use of morphine and scopolamine in proper dosage as a preliminary to the larger operations under local anaesthesia.

Spinal anaesthesia is another procedure that has a very distinct place. I have rather strong opinions on this subject. Statistically it is much more dangerous than most general anaesthetics or novocaine locally, but in given cases I believe that it is much less dangerous. Especially is this true of operations on the prostate and the more serious operations on the rectum. It is also the anaesthetic of election in diabetics where the field of operation is not too high, and it must be considered in cases with pathological lung conditions.

There is one very considerable advantage that these forms of local anaesthesia have over general inhalation anaesthetics. Of themselves they do not interfere with the taking of regular and sufficient food, which may be of greatest importance.

Nitrous oxide and nitrous oxide-oxygen are anaesthetics that are not properly considered in our selection. Both have been sadly neglected except by those men who have the nitrous oxide-oxygen hobby, and by those few have at times been over-done, so that I think we all share a prejudice against the use of nitrous oxide-oxygen. The truth is we do not know all we should about nitrous oxide-oxygen, and I must confess that I advise its use only in a very limited number of cases. In general, these are cases in which the operator does not require muscular relaxation and where the operation requires only a short anaesthesia. It now seems crude in most cases for anyone to do a paracentesis of the drum without an anaesthetic or a dilatation and curettage under ether when nitrous oxide-oxygen is available. I mention only these two operations,

but of course there are many others where it is an excellent anaesthetic both for the patient and the operator, and does away with some of the discomfort of most general anaesthetics.

As to the actual giving of the anaesthetics, there are only a few things that need to be said. One must remember that all anaesthetics are poisons with the possible exception of nitrous oxide, and therefore, the less taken by the patient the better. This being the case a position on the table which gives muscular relaxation, and surgical technique which does not require profound anaesthesia are always desirable. It is never wise, however, to hurry the induction of the anaesthesia. One anaesthetic method that I wish to call particular attention to is the method of rebreathing or closed method. Some anaesthetists boast of the small quantity of ether required by this method. It is true that a much smaller amount of ether is added to the inhaler, but it is also true that, where asphyxia plays no part in the maintenance of this anaesthesia, the patient is still getting 15% by weight of ether vapor, the only difference being that the ether exhaled by the patient is again inhaled with this method instead of being thrown off into air as in the open method. I said "if asphyxia played no part in the anaesthesia," but as the method is usually applied asphyxia does play a part, and a part that is far from desirable. Patients anaesthetised by the closed method are frequently a little off color and I believe that they have a greater amount of anaesthetic shock or fatigue. I do not wish it understood that rebreathing has no place in the giving of anaesthetics—this is not true, but when rebreathing is used the oxygen content in the mixture must be maintained as high as in the surrounding air and we must realize that although the amount of ether added to the inhaler is much less than by the open method, the per cent. inhaled by the patient must be approximately the same. What, then, are the advantages of using this method in any cases? According to Henderson's theory a certain increase in the amount of carbon dioxide inhaled combats the state of shock. While I do not entirely believe in all of Henderson's deductions, it is clinically true that in some cases a condition which we call shock is somewhat relieved by an increase in the amount of carbon dioxide inhaled. We can, however, maintain a proper oxygen content while still increasing the amount of carbon dioxide. This leads to a consideration of the condition of shock. There is probably no more disputed phenomenon in the whole realm of surgery, and when we collect all the real facts about it we have very little to show. Of course shock is a real condition, but of the mechanism of shock we know very little. Crile's theories, while they are in part true, are not the whole story by a long way. Personally I think there are two, sometimes distinct, states. True, surgical shock, which is due in part to hemorrhage and in part to trauma, causing afferent nerve

impulses which result in exhaustion of the central nervous system. There is, however, another state resembling shock in which these factors play but little part. This is due to the length of the operation and certain factors in the course of the anaesthesia. I prefer to call this condition fatigue, though whether it differs in kind or only in degree from true surgical shock, I cannot say.

The operating table and the patient's position on the table are other matters about which something should be said. Is there any reason why the operating table should be so uncomfortable? Why not have pads on it thick enough to take off some of the board-like feeling and which will, to a certain extent, prevent the radiation of heat from the patient's body? In most hospitals they put a small pad under the lumbar curve of the spine so that when muscular relaxation comes on, this lumbar curve is maintained and there is less strain on the back. Placing a pillow under the knees is of almost as much importance in preventing the post-operative backache, and has the advantage that it promotes relaxation of the abdominal muscles, thus giving the surgeon more room in abdominal work. Let me say one word about the Trendelenburg position. As it is usually carried out, the legs are flexed at the knees. This in itself puts a marked strain on the abdominal muscles, requiring a much deeper anaesthesia to give the required muscular relaxation. It also puts an added strain on the back and is a contributing factor to backache in these cases. I believe that it is very much better to use well padded shoulder pieces and keep the legs out straight, even at a slight inconvenience to the surgeon. If you have never laid on a table in the Trendelenburg position, with the legs down, I think you will be quite surprised at the amount of muscular tension this position gives. One should avoid whenever possible any position placing the muscles in strain while under an anaesthetic as we do while conscious.

As before stated, the anaesthesia should be as light as possible. Certain unnecessary factors in operative technic make it necessary at times to carry the patient along in a deeper stage of anaesthesia than is desirable. Rough handling of wounds and of the abdominal organs makes it necessary to have a much deeper anaesthesia than careful handling would require. While I am strongly in favor of rapid operating, I feel sure that it is rarely, if ever, necessary to be rough. This rough handling not only requires a deeper anaesthesia, but even when the anaesthesia is deep enough to maintain muscular relaxation the amount of surgical shock is markedly increased. In certain regions and in certain procedures it is particularly desirable to be gentle. Any traction on the intestines or stomach should be particularly gentle. I have seen an abdominal retractor put into a wound and given a jerk in retracting the muscles and peritoneum that caused an immediate spasm of the muscles and an

amount of shock that was almost unbelievable. The same thing may occur if a loop of intestines is pulled roughly out through a small wound. In this connection let me command the self-retaining retractor, which gives retraction without the intermittent pulls and jerks, each one of which acts as a direct stimulus to the contraction of the muscles pulled upon. It is not cutting that causes shock, but pulling and other manipulation. One should be as careful to handle tissues gently under a general anaesthetic as one is under local anesthesia, if the best results are to be obtained. I have but one word more to say about technic. Surgery is done primarily for the benefit of the patient. When the patient is ready to be prepared the attendants should be ready to do the preparation, and the surgeon should be ready to commence the operation as soon as the patient is deeply enough anaesthetized to allow it.

Post-operative care is another matter for consideration. Fortunately there have been great advances in the last few years, and some of the absurdities of the older post-operative treatment have now become obsolete, such, for instance, as withholding water. If there is any one time when a patient needs water it is after operation. He needs fluid to make up for loss by bleeding and by perspiration. The fluid taken also dilutes toxic substances absorbed from the intestines so that they are eliminated with less irritation by the kidneys. I believe that there is less nausea and vomiting where water is given. The quantity of fluid vomited may be greater, but the vomiting is of shorter duration and the straining is less. Whenever vomiting persists acidosis should be suspected and prompt measures for combating this condition should be instituted. It is much better to prevent acidosis by proper diet before operation than to cure it after operation, but in cases where proper diet cannot be given before operation we can usually relieve the condition quite promptly afterwards. Irrigation of the colon with sodium bicarbonate water (3 teaspoonsful of sodium bicarbonate to 2 quarts of warm water) followed by a nutrient enema of 5% dextrose solution will usually relieve the condition quite promptly. Feeding a patient broths just before and just after operation is one of the absurdities that we will see entirely disappear within the next few years. They have almost no nutrient value, they throw considerable work upon the kidneys, and they do not greatly relieve hunger. Why should we give them at all? The only possible excuse is that they do not leave any residue in the intestines. Carbohydrates should be given, and when they cannot be given by mouth in sufficiently large doses they should be given by rectum.

Let us again consider the question of back-ache. Proper position on the table is not always enough to prevent this, and it is well to be sure that the back is not in a position of strain when the patient is returned from the operating room

to the bed. A pillow under the knees helps. Frequent changing of the patient's position is also of assistance.

As you see, this paper makes no pretense of being exhaustive. It is intended to call attention to certain neglected procedures and to promote discussion of our present methods, which it is hoped will be for the best interests of our patients.

EPISIOTOMY.

BY JOHN T. WILLIAMS, M.D., BOSTON,

Fellow in Gynecology, Harvard University; Third Assistant Visiting Surgeon for Diseases of Women, Boston City Hospital; Assistant Surgeon, Gynecological Department, Boston Dispensary.

THE purpose of this paper is to renew attention to a little-used procedure of definite value in certain obstetric cases. Episiotomy was first suggested by Ould¹ in 1742, and again by Michaelis² in 1810, but received little attention until about 1885, when the operation was taken up by Credé³, Manton,⁴ and others.

It was at first used to substitute a clean incised wound for the lacerations of the perineum. But as improvement in the after-care made union after a primary perineorrhaphy possible, the operation fell into disuse. Episiotomy today has one indication, namely, the prevention of complete tears of the perineum.

While with improved obstetric technic complete lacerations of the perineum are less common than formerly, there are still occasional cases in which these are unavoidable except by the increase of room afforded by section of the soft parts in a lateral direction. According to Williams⁵ a large part of all complete tears are the result of contractions of the inferior strait of the pelvis. To this must be added the rigid perineum of the late primigravida, the short perineum where the distance from the fourchette to the anus is very short, unusual size of the fetal head, the aftercoming head in breech presentations and face presentations delivered as such (Edgar⁶).

It is desirable for good approximation that the incision should be made before the perineum starts to tear. Practically it will be often necessary to make use of this procedure after laceration has commenced. In this event the incision should be made from the edge of the tear rather than from the original margin of the vulva.

ANATOMY.

The soft parts of the vaginal outlet may be divided into two parts:

1. The levator ani.
2. The small perineal muscles and the fibrous tissue and fasciae making up the perineal body.

The levator ani, or rather that part of it which Savage⁷ has named the pubo-coccygeus, arises from the posterior surface of the os pubis and extends backward about the vagina on either side to be inserted into the tip of the coccyx and the fibrous body of the perineum. This muscle can be palpated about one inch inside the introitus vaginae, and should not be

The perineum proper consists of two small muscles, the sphincter vaginae and transversus perinei, which, with some fibres from the levators, blend in a mass of fibrous tissue known as the perineal body, which is connected with the lower borders of the rami of the pubis and ischium by several indistinct fascial planes, analogous to the superficial perineal fascia and triangular ligament in the male. The incision should divide these parts.

TECHNIC.

The incision should be made at an angle of about 45° with the median line of the perineum, and not at a right angle, in order to avoid wounding the venous plexus of the labium and to give the greatest room for extension. It is most easily performed with sharp, long-bladed, blunt-pointed scissors.

Jewett⁸ does the operation bilaterally. Usually, however, it will be necessary to incise only one side. Waldstein⁹ makes a median incision half way through the perineal body, and then extends the incision at right angles on either side. The repair after such an incision is, however, extremely complicated.

The suture of the episiotomy incision is rather difficult, and involves suture of the vaginal and perineal aspects of the incision with interrupted sutures of catgut and silkworm gut respectively. Placing the stitch first, which embraces the junction of the skin and vaginal mucous membrane, greatly facilitates accurate approximation.

The after care is the same as that of primary perineorrhaphy. A slight experience with the operation will convince one of the advantage of performing episiotomy over allowing the perineum to tear into the rectum. The writer has done episiotomy in a number of cases from which he has selected two as illustrative of the whole group.

CASE 1. Mrs. L., a muscular primipara of 25, after a tedious labor of 20 hours was delivered by forceps. The perineum was extremely rigid and undilatable. Realizing that a tear through the sphincter would otherwise be inevitable, the soft parts were divided to the left for a distance of one inch. Delivery of a living 7 lb. baby was completed without further damage to the soft parts. The episiotomy wound was sutured and united by first intention. Four years later the patient was delivered normally of a $7\frac{1}{2}$ lb. baby. Episiotomy was not performed because the labor had proceeded so rapidly that there was not time to fully anesthetize the patient, and a tear into the sphincter resulted, which fortunately, however, united by first intention.

CASE 2. Mrs. S., a large, well-formed primigravida of 24, was delivered by low forceps after a sixteen-hour labor. In spite of the greatest care the perineum started to tear, and realizing that extension through the sphincter was inevitable, the

S.A. sphincter ani.
L.A. levator ani.

cut in performing episiotomy. Schuchardt's incision, which is sometimes made as a preliminary to vaginal hysterectomy to allow a wider access to the vagina, does divide this muscle.

soft parts were divided to the left of the perineum. Delivery of an 11½ lb. baby was then accomplished without injury to the sphincter. Healing of the episiotomy incision was complicated by suppuration, resulting in partial breaking down of the wound. This, however, gave no loss of support, and the breaking down of a complete perineal suture, which would have happened just as surely, would have meant a period of fecal incontinence, followed by the discomforts and difficulties of a secondary operation. Sixteen months later she was delivered normally of a baby 2½ lbs. smaller than the first, without further laceration.

CONCLUSIONS.

1. Episiotomy is a procedure of definite value.

2. Properly used, it should practically eliminate complete lacerations of the perineum from gynecology.

3. It should not be performed except to prevent a complete tear, because incomplete perineal tears heal as well as the episiotomy wound and are less difficult to suture.

4. Complete lacerations of the perineum are especially to be feared in:

- (a) Contractions of the inferior strait.
- (b) Rigid perineum, as in late primigravidae.
- (c) Short perineum.
- (d) Unusual size of fetal head.
- (e) Aftercoming head in breech presentation.
- (f) Face presentations.

WANTED—A FAD!

By ROBERT T. EDES, M.D., READING, MASS.

THIS "ad." among many others in the columns of a paper which I had supposed to have as little occasion to feel such a want in this, its home district, as any other known to modern civilization, a region or soil producing as luxuriant a crop of such unhealthy vegetation to the square acre of "witch grass," "artemisia," "ambrosia," or other weeds under names very far in excess of their merit, struck me as amusing at the time, but later more seriously in the form of a short-notice call from the secretary.

This "ad." brought out some very excellent advice, as I ascertained from subsequent numbers of the paper, but it was under false pretences.

Why should any sensible person ask his fellow reader to tell him what "trivial fancy" to adopt or what "imperfectly understood matter" he had better "pursue with more zeal than reason"? I am quoting these definitions from the "Century Dictionary." You will not find the word in the "Webster" as late as 1873, although "fiddle faddle" is there on authority as old as the *Spectator*. The most zealous faddist would not welcome suggestions under this definition.

What this enquirer wanted was not a "fad" at all. He wanted, or at any rate deserved to get, a "hobby." He might have got many times more than enough value to pay the expense of the advertisement.

There is not much to be said in defence of the mere fad. In its earlier growth, until it attains the greater dignity, it may be as harmless as tiddly-winks or cat's cradle, less dangerous than "bridge," and as useful as the knitting of pretty woollens for the unborn babe. It may supply a long-felt want,—a cerebral vacancy.

A retired adjutant of the United States Army during the Civil War once exhibited to me with some pride his collection of postage stamps, among which one of the specials was an imperfect one of, I believe, a Central American republic. It might have been this fad, as well as his sense of official propriety which headed him off from publishing a book of "reminiscences," which would have been far from being as harmless either to himself or to many others as tiddly-winks.

A nervous young lady once complained to me, while talking over her plans for the coming season, as if the choice of a career were freely open to her, "I'm going in for art this winter. I tried charity last winter, and it didn't work." Neither worked very well for the poor girl, though her charity did but little harm and her art was equally innocent. Whether her "nervousness" had anything to do with a hypertrophied spleen, from which she had recovered, or to the well-marked typical case of exophthalmic goiter which afterward developed, I cannot say; it is not impossible that there may have been some remote connection with the latter.

But the sanely developed side occupation, the by-product of the work by which one earns,—or tries to earn,—his daily bread, the amusement, the relief from wearing monotony of toil, which gives no mental stimulus, but allows no relaxation of attention; the *hobby*, changing the perspective and giving the worker a different outlook at life, is something much more worthy our attention.

The hobby may indeed outgrow itself, and become the serious work, just as in manufactures it is sometimes the by-product which gives the profit. A large part of literature teems with ex-

amples taken from all walks of life, the professions, the arts, trades, and handicrafts or even the leisure which might have gone to mere amusement but has become a willing sacrifice to more congenial work. But these examples are taken to show that the plough horse can keep on doing his good work, none the worse for the hobby frisking alongside. Whether the relief asked for or given be philosophy, or philanthropy or literature,—read or made,—or a handicraft demanding skill, or the pursuit of science or a simple game, it should be followed as a hobby to be ridden carefully or mercifully. "Whatever thy hand findeth to do, do it with thy might," is a precept to be accepted with discretion, according to one's strength, and not by the blind following of the strenuous worker, the exceptional man or woman, whom nothing can tire. He is much more rare than his would-be imitators. He is a dangerous guide. It is "*thy*" might after all and not the might of the "don't worry" books.

There is such a condition as "neurasthenia," however much that misused word has been made the cover of foolish and ineffectual strain or, on the other hand, of incipient mental disease, or of mere indolence. But it is not so much the man of hobbies upon whom it comes as upon the man, the woman, driven by need or by conscience, to wearing overwork in a single direction or a more wearing responsibility, who cannot give herself the relief of the hobby, or even of the fad.

A distinguished educator in a discussion with a leader of labor ("*Labor*" in the official sense) said, in one of those lapses which even so clear a thinker and speaker as he is liable to make sooner or later, that the "joy of the labor" is a part of its compensation, neglecting the difference between the direction of a great educational institution, the upbuilding of which had been his life work, and on the other hand the dropping for hours, months and years into a machine of bits of metal to turn them out just alike; or the planning of a great business compared with the shoving for hours of the same sized bars through the same rollers, for the same wages—probably considered inadequate—or even, to come nearer, the leading of zealous students in fruitful research, and reading the examination papers of the dull average not good enough to be interesting nor absurd enough to be amusing.

President Eliot was right from his point of view; but the labor leader was unconvinced from his, *as he had a right to be*. He ought not to be content with his kind of work. He should have a hobby. I do not remember who he was, but perhaps his employment as a representative spokesman rather than an actual daily worker may have acted as his hobby and been the needed relief for him. If otherwise, a literary hobby, say the study of history rather than the reading of political economy or one-sided sociology; or better still a thorough out-door

hobby in which he should take an active part and not be contented with seeing others play, would tend to a healthy mind. For the brain-fagged, the two-sided outdoor hobby is the ideal, in which one learns something as well as makes something, puts the commonplace donkey-rider in the same class as the discoverer and the doer.

Who is the brain-fagged? A young girl in the hospital told me that her doctor had told her her "brain was all worn out." Further inquiry disclosed that her occupation had been pasting labels onto shoes.

The man who needs to "take no thought for the morrow, what he shall eat or what he shall drink, or wherewithal he shall be clothed," if he have no ambition to rise further in the same direction, must have a hobby for the salvation of his mind, his heart and his happiness. He may make a hobby of anything, even of the essentials of life. Even so the bon vivant, the epicure, is better than the mere gormandizer or the drunkard. The dandy is a thing of greater joy to the public, even if not very important, than a careless sloven. If it is salvation to the man himself to have almost any reasonable hobby, it is an enduring joy to him and great profit to the world, that he should have one adapted to his talents and of altruistic direction. Fortunate for our country that the idle man is not the type held up for admiration before any but a very small fraction of the people, and that usefulness to others does not detract from the esteem in which the busy man is held.

But for the brain drudger, the accountant who feels when he has got to the end of his work day, that he cannot look at another figure, the typewriter whose machine has begun to dance over the table, the selector of colors to gratify an endless procession of different tastes, where each knows less than her predecessor, and so on down to the merest shoveler of gravel, needs a change from the day's work. In a vast proportion of cases this is merely amusement and nothing more. All work, be it little or great, is as nearly as possible stopped. Of course it is only the favored few who can have this, but it is not necessary, perhaps not even desirable, that every grade of mental activity should always be reduced to zero.

Biologic science naturally, almost inevitably, appeals most strongly to the medical practitioner, even in departments considerably removed from his daily work. He cannot help thinking of eugenics, for instance, and may make the most important contribution to that old—old but newly-named—branch, which he has constantly before him in every shape of diagnosis, pathology and therapeutics. If his daily practice enables him to straighten out some few threads of generalization, he is fortunate. The hereditary family practitioner has the best of opportunity among his human subjects and is the best man to look at this branch from all sides. Who but he can follow out the "dominant" and "reces-

sive" influences in the Mendelian maze, now left so largely to the novelist?

But if he follows beyond his own species, his range becomes wider and more generalized—as in botany and gardening. On the humbler side also it has its uses. I remember a good many years ago hearing a most philosophic practical surgeon, in sketching an ideal medical course, place a very high estimate on botany, among the elementary studies; but for what reason, think you? Because it gave the student useful practical knowledge of *materia medica*. I felt for years later that our honored colleague was making a mistake, in these days when the druggist is the man to *know* about drugs and can get his recreation elsewhere. Even he, as a rule, knows none too much about them beyond the name printed on the bottle. I was gratified to find myself justified in placing a more worthy estimate upon this study when I found these phrases in an appreciation of Sir William Gowers, one of the foremost of English neurologists, as follows:—

"The process of identification of plants by the descriptions, the training it involves in accurate observation and in giving the proper relative weight to different features is essentially the same as that which is needed in the diagnosis of disease. No subject affords mental training quite so effective for the practitioner's work." This remark was from a man who had taken shorthand notes on more than twenty thousand cases of nervous diseases.

How many thousands of physicians could we reckon, without going far into the past, who have been adepts in botany, who beginning perhaps in the *materia medica* point of view in their own gardens have derived lessons of biology of the higher interests to mankind. And we needn't go far to find botany linked with the widest, most far-reaching generalizations through the names of Agassiz, Gray, and Darwin. It is interesting to speculate on the reactions between Dr. Jacob Bigelow's "*Florula Bostoniensis*," his later works on Medical Botany, and his views in still later life on Nature in Disease and a more rational and scientific treatment.

As he gathered his specimens driving along the muddy roads "within four or five miles of Boston" more than a hundred years ago, did the thought enter his mind, "Let the children go without herb teas for a while. They will probably get well just as quick."

Such doubts as these seem also to have entered into the views of Dr. Alfred Stillé between the publication of his elaborate work on *Materia Medica* and Therapeutics, and that of the American Dispensatory.

Dr. H. C. Wood became a member of the National Academy of Science, not on account of his learned work on Therapeutics, but for his earlier knowledge of mycology.

Several of the official reports on the natural history of Massachusetts were prepared by active practitioners of medicine; that on Fish by Dr. Storer, professor of midwifery, that on Shells by Dr. A. A. Gould, one of the physicians of the Massachusetts General Hospital. I am not sure that Dr. Thaddeus William Harris, who prepared a most valuable work on "Insects Injurious to Vegetation," was a practitioner, although he was a graduate in medicine. He was for many years librarian of Harvard College.

George B. Emerson, author of the report on Forest Trees was for many years the leader of a well-known girls' school in Boston.

John E. Holbrook, who published an illustrated book on Herpetology, which was for many years the authority on the subject in the United States, was a professor of anatomy in the medical college of South Carolina.

Military glory has attracted more than one practitioner away from too strict devotion to business. Let us mention here the name of Major-General Dr. Appleton Howe of South Weymouth, of whom Dr. Jarvis remarked, "When he has on his uniform and draws his sword we do not dread him in the least, but when he takes up his lancet then we are afraid of him."

There may be one or two of us oldsters who have seen the little red tails of our beloved member, Lieutenant Col. Dr. C. C. Holmes' short jacket flopping briskly up and down against his plump posterior as he led the Cadets at double quick round the common. When he was one of Governor Andrews' trusted military advisors he had to say that he had had great numbers of requests for his interest in getting commissions for boys, none of whom had had anything approaching the experience which the business men are now getting at Plattsburg,—the successful ones got it later,—and he used to write letters telling the governor what fine fellows they were and how justly proud their fathers were of them; but it was understood that unless they ended with the phrase, "And I advise you to take him," they went for nothing. It is pleasant to think that his sacrifices to Mars never lost him many patients from Lucina.

And we must not forget that the ranking officer of the United States army was once an intern of the Boston City Hospital, entered the army through the medical corps, and that both his medical and military knowledge have been of the highest service.

Sir Robert Christison must have been a great ornament and delight in the profession at Edinburgh, where he lent dignity and learning to more than one professorship, was the author of a treatise on "*Materia Medica* and Toxicology," and another on "Bright's Disease," an experimenter in his own person on numerous drugs, and an expert in court so exact and so clear that

he habitually escaped the heckling to which other less careful men have to submit. He was an athlete of renown through his long life, as a walker, a sprinter, and mountain climber, while his stately figure and flowing white locks made him a marked man as he stood on parade at the head of his company in the University Battalion at the age of seventy-seven.

Aquatic sports have attracted many of our profession. New England's sea coast has been the playground of some of us, as is befitting in those of Cape Cod lineage. I have myself taken many a rest as opportunity has offered, both with oars and sails, from the Charles to the Mississippi. The good which comes from rowing, both physically and mentally, cannot be half so graphically set forth by anyone else as by Dr. Holmes, and I will quote a little more at length from his description of his voyages of discovery over the flats of the Charles River when it was a river, long before it had become a fresh water basin. The wherry in which he voyaged I used to see in the cellar of the old, not the most recent "old," but the old "old" medical school in North Grove Street, as I passed through it to the dissecting room.

"Here you are, then, afloat with a body a rod and a half long, with arms, or wings, as you may choose to call them, stretching more than twenty feet from tip to tip; every volition of yours extending as perfectly into them as if your spinal cord ran down the centre strip of your boat, and the nerves of your arms tingled as far as the broad blades of your oars,—oars of spruce, balanced, leatherned and ringed under your own special direction. This, in sober earnest, is the nearest approach to flying that man has ever made or perhaps ever will make.* As the hawk sails without flapping his pinions, so you drift with the tide when you will, in the most luxurious form of locomotion indulged to an embodied spirit. But if your blood wants rousing, turn round that stake in the river, which you see a mile from here; and when you come in in sixteen minutes (if you do, for we are old boys, and not champion scullers, you remember), then say if you begin to feel a little warmed up or not! You can row easily and gently all day, and you can row yourself blind and black in the face in ten minutes, just as you like. It has been long agreed that there is no way in which a man can accomplish so much labor with his muscles as in rowing. It is in the boat, then, that man finds the largest extension of his volitional and muscular existence; and yet he may tax both of them so slightly, in that most delicious of exercises, that he shall

mentally write his sermon, or his poem, or recall the remarks he has made in company and put them in form for the public, as well as in his easy-chair.

"I dare not publicly name the rare joys, the infinite delights, that intoxicate me on some sweet June morning, when the river and bay are smooth as a sheet of beryl-green silk, and I run along ripping it up with my knife-edged shell of a boat, the rent closing after me like those wounds of angels which Milton tells of, but the seam still shining for many a long rood behind me. To lie still over the flats, where the waters are shallow, and see the crabs crawling and the sculpins gliding busily and silently beneath the boat: to rustle in through the long marsh grass that leads up some tranquil creek; to take shelter from the sunbeams under one of the thousand-footed bridges, and look down its interminable colonnades, crusted with green and oozy growths, studded with minute barnacles, and belted with rings of dark mussels, while overhead streams and thunders that other river whose every wave is a human soul flowing to eternity as the river below flows to the ocean,—lying there moored unseen, in loneliness so profound that the columns of Tadmor in the Desert could not seem more remote from life, the cool breeze on one's forehead, the stream whispering against the half-sunken pillars,—why should I tell of these things? That I should live to see my beloved haunts invaded and the waves blackened with boats as with a swarm of water-beetles? What a city of idiots we must be not to have covered this glorious bay with gondolas and wherries, as we have just learned to cover the ice in winter with skaters!"

Our old teacher of anatomy and of social philosophy speaks of some other forms of exercise with modified respect, but his summing up, "I am satisfied that such a set of black-coated, stiff-jointed, soft-muscled, paste-complexioned youth as we can boast in our Atlantic cities never before sprang from loins of Anglo-Saxon lineage," reads very queerly in the light of the "athletic pages" of our daily press. The "aerial swimming," which he speaks of as what "some fancy is to be a conquest of the future," he came within but a few years of seeing.

Is it possible that the lure of salt water had any share with philanthropy in making Grenfell the guardian angel of Labrador?

Probably a very much larger proportion of physicians have made side excursions into more or less unprofessional literature than into any other so easily accessible.

The greatest of the poets, whom even the most liberal construction will allow us to reckon as a disciple of Aesculapius, was Schiller, who was indeed rather a forced recruit, for he was not very far beyond his boyhood when he was driven

* "The boat flies like a sea-bird with its long, narrow, outstretched pinions; the bicycle rider, like fethered Mercury, with his wings on his feet. There seems to be nothing left to perfect in the way of human locomotion but aerial swimming, which some fancy is to be a conquest of the future."
Will the chug-chug boat drive rowing to become a mere specialty among the higher universities?

from his post of ill-paid army surgeon at the age of twenty-three, to rise rapidly to the first rank in literature, long before he could have suffered from the monotony of medical life.

Poets of a lesser rank on both sides of the water could undoubtedly be reckoned in large numbers by those more learned than myself.

Smollett, who for many years thrived only moderately as a practitioner, held for a time the position of the first of English novelists.

Akenside, who is described in the *Encyclopedia* as an "acute and learned physician," and who was made, for political reasons, physician to the queen, and his political works included in an edition of the British poets, had an unsympathetic character and a sarcastic style which prevented the success to which his learning and ability entitled him.

On this side of the water one has but to mention the names of Holmes and of Mitchell as worthy the highest honors in both professions. It is said that Mitchell asked Holmes' advice,—being much the younger man,—as to adopting literature as a profession and was advised against it, which has been a great gain to neuropathology, certainly with no corresponding drawback on the other side of his work. The work of Mitchell has been of the best, but he will probably be remembered, even among the novel readers of his own profession, for his work on "Injuries to Nerves" and his "Fat and Blood and How to Make Them," more than for his novels.

I do not think Holmes was ever more than a moderately successful practitioner, but soon became, outside of his specialty, almost exclusively a literary man, never, however, losing his interest in medical science. It was said that he himself claimed more credit for his work on the contagiousness of puerperal fever than for anything else he had done.

In the broad field of letters, where he so frequently and delightfully appeared as physician, essayist, social critic, and philosopher, where pseudo-science was ruthlessly punctured, medieval theology and medieval medicine good-naturedly satirized, and where too confident youthful enthusiasm was good-humoredly rebuked, he was inimitable. If he had a weakness on this field it was in his inability to resist the temptation to sacrifice scientific accuracy to an epigram. I was fortunate enough to hear that address to the Massachusetts Medical Society which deeply wounded some of his less progressive brethren, but which has been incorporated into so much of present-day practice; a recent re-reading only increases my respect for its sound sense and scientific accuracy as well as its rhetorical charm.

NOTES OF A CONFERENCE ON THE MEDICAL AND SOCIAL ASPECTS OF SYPHILIS OF THE NERVOUS SYSTEM.

HELD AT THE PSYCHOPATHIC HOSPITAL,
MAY 27, 1915.

(Continued from page 922.)

V.

MENTAL FEATURES OF CONGENITAL SYPHILITICS.*

By J. H. BAZELEY,

Student Harvard Medical School, and Interne,
Psychopathic Hospital,

AND

H. M. ANDERSON,

Social Worker, Psychopathic Hospital.

CONTENTS.

- I. THE MENTAL PHENOMENA IN GENERAL MENTAL STATES AS RELATED TO CONGENITAL SYPHILIS.
- II. THE MENTAL PHENOMENA IN SIXTY CONGENITAL SYPHILITIC CHILDREN COMPARED WITH SIXTY NON-SYPHILITIC CHILDREN.
- III. THE MENTAL PHENOMENA IN FAMILIES WITH CONGENITAL SYPHILITIC CHILDREN.
- IV. CONCLUSIONS.

i.

THE purpose of this paper is to draw attention to the pathological mental phenomena in congenital syphilis. For a long time there has been a more or less generally recognized group of mental conditions that were ascribable to this factor in heredity, but of late years there has been a more specific recognition both of the disease and its immediate connections. Very many of these abnormal mental conditions are acquired early and before the brain has completed its development. Others are of a less tangible nature and have not been definitely associated with syphilis. If one considers the four main types of abnormal states; namely, psychoses, feeble-mindedness, delinquency, psychoneuroses, one can trace something more than the former indefinite associations. Many of these conditions come in middle life and are ascribable to some endogenous factor. The grounds on which feeble-mindedness is related to syphilis are many and have for a long time been recognized. Delinquency can be ascribed to syphilis only as the two

* Being S. B. I. Contribution whole number 126 (1915.29). (Bibliographical Note.—The previous contribution by Donald Gregg, entitled "A Few Economic Facts of the Syphilis Problem from the Psychiatric Side," BOSTON MEDICAL AND SURGICAL JOURNAL, Vol. clixiii, No. 25, p. 921.)

are connected with some kind of emotional instability or some psychopathic inferiority. The percentage of delinquents who are actually feeble-minded is probably around 15 or 20, but outside of this there must be a larger group of 30 or 40% which is connected somehow with constitutional psychopathic inferiority. At the most, it would be extravagant to say that more than 30% of the delinquents could be connected with congenital syphilis. In regard to the endogenous psychoses and the psychoneuroses, there is good ground for definite causal relation. Mott has pointed out that it is the tendency of such a psychosis as dementia praecox to die out of the race, as its earlier appearance in successive generations causes the stock to cease to propagate. But as this psychosis seems to be on the increase, there must be some extraneous factor producing it anew. This factor, he suggests, may be syphilis. Meggendorf comes to a similar conclusion after a somewhat protracted study. Freud states that in more than one-half of the severe cases of hysteria, compulsion neuroses, etc., which he had treated by psychotherapy, he positively succeeded in demonstrating that the fathers had gone through an attack of syphilis before marriage; they had either suffered from tabes or paresis or there was a general history of lues. He expressly adds that the children who were later neurotic showed absolutely no signs of hereditary lues, so that the abnormal sexual constitution was to be considered as the last offshoot of a luetic heredity.

There is a similar truth in the overstatement of Dr. Thomas at the Alameda County Medical Association in December, 1912. He affirmed the clinical evidence of the stigmata of syphilis to the third, fourth, and even later generations; claimed that neurasthenia is absolutely caused by syphilis, being a distinct physical disease of the brain and cord; and stated that non-syphilitic alcoholic parents do not beget the idiotic, defective children, but rather the alcoholic syphilitic parents do.

Besides these speculations which have become more definite in our day, there is a certain number of conditions in which the effect of the inherited syphilitic taint can not be doubted. Our interest in this paper will lie in the mental development of these congenital syphilites. First, it is necessary in each case to be sure of the diagnosis, and in the past this has been done mostly on the basis of observation. It is unnecessary to review these various stigmata on which one can make a positive diagnosis. Before the laboratory tests, this was the only means beside the family history of making a diagnosis, and consequently these stigmata have been carefully denoted. When certain of the most characteristic signs are present, there can be no reasonable doubt as to the existence of congenital syphilis. Thus the presence of the Hutchinsonian triad is sufficient for diagnostic purposes. The second method of diagnosis was from a fam-

ily history of syphilis, numerous miscarriages, and numerous still-births, but the literature affords us plenty of evidence that this is not sufficient ground. The third method, namely the Wassermann reaction and the examination of the cerebrospinal fluid, is more definite and accurate, and has added much to our diagnostic ability. On the basis of these three methods of examination, viz: the laboratory tests, the physical stigmata, and the positive family history, it is possible to make the following division in cases of congenital syphilis:

Group 1.

- a. Those with a positive spinal fluid which would include such types as juvenile general paresis, juvenile tabes dorsalis, epilepsy and cerebrospinal syphilis.
- b. Those with a negative spinal fluid including such types as optic atrophy (optic tabes), epilepsy and hydrocephalus.

Group 2.

- a. Those in which the blood is positive and the physical stigmata are present.
- b. Those in which the blood is positive and the physical stigmata are absent.
- c. Those in which the blood is negative but the physical stigmata are present and the family history is positive.
- d. Those in which the blood is negative and the physical stigmata are absent but the family history is positive.

One could not expect to find different types of mental conditions corresponding to this grouping, but this grouping is serviceable in indicating the degree of physical and mental disturbances and allows a more definite determination than we have hitherto used in the study of a group of this disease. Different cases might be cited to show the abnormal or deteriorated mental symptom in the individuals in these groups but the variations on the mental side are too numerous to parallel the laboratory and physical determinations.

In order to ascertain how the mentality of congenital syphilites compared with non-syphilites, some 440 hospital cases were gone over and it was found there were 60 under 15 years of age who could be put down as definite congenital syphilites. Along with these, 60 non-syphilitic cases were taken for the sake of comparison. In every case the laboratory tests had been made, a male was matched with a male, a Russian with a Russian, and one of 10 years with another of 10 years, and in the whole series of 120 there were only three instances where it was impossible to match for age, sex and nationality. There were nearly a dozen instances in which a choice between two was possible, but in every such case the latest was taken, since in these the examinations are more thoroughgoing. The 60 congenital syphilites

were found to group as follows, and it was pure chance that they turned out to be 30 males and 30 females:

GROUPING OF 60 CONGENITAL SYPHILITICS BASED ON
LABORATORY FINDINGS

	M	F
I. Fluid		
a. Positive	1	1
b. Negative with Phys. Stig.		3
II. Serum		
a. Positive	5	10
b. Positive with Phys. Stig.	13	13
c. Negative with Phys. Stig.	9	0
d. Negative with Family History	2	3
	30	30

ii.

The comparative mentality of these 60 syphilitics with 60 non-syphilitics is shown in the following summarized statistics in regard to *development, diagnoses, defects in sense organs, defects in mental processes, and delinquencies*.

In regard to *development*, it seemed best to take the Binet age, since these cases go back nearly three years and in every case the Binet had been done, whereas the Point Scale had been applied only in the last year. The average age of the syphilitics and non-syphilitics was, of course, the same, namely, 10.3 years. The average Binet age of the syphilitics was 6.2 and of the non-syphilitics 7, so that the deficiency among the former was 4.1 years as compared with 3.3. Next, the school grades were considered and among the syphilitics there were 36 cases of backwardness in school as compared with 24 cases in the non-syphilitics.

The *diagnoses* were considered either *feeble-minded*, which was taken to be a mentality below 12 years, or at least two years below the actual age, along with indications of feeble-mindedness on family, social, economic and moral lines; or *retarded*, which meant not sufficient to be called feeble-minded yet behind the actual age, and of these cases some eventually become feeble-minded; or *defective*, which meant neither of the above but a subject having some special defects in the larger mental processes which came to the front in the examination; or *normal*; or *supernormal*. The results of the 120 individuals differentiated on these grounds are as follows:

	Syphilitics	Non-Syphilitics
Feeble-minded	29	25
Retarded	19	12
Defective	4	7
Normal	6	14
Supernormal	2	2
	60	60

Next, the *defects* in the sense-organs of vision and hearing and the development of speech were considered, since any handicap in these manifests itself in the mental development. In re-

gard to speech there were nine syphilitics compared with none in the non-syphilitics. The fact of this disproportion and the preponderance of speech defects over vision and hearing give some support to a point recently put forth by Dr. Walter B. Swift in the Pediatric Society meeting for April, to the effect that there was a distinctive voice sign in congenital syphilis. This he characterized as having a certain roughness and harshness, and a certain inability to go from a low to a high pitch, and return. He emphasized the characteristics and this examination shows the frequency of defects in speech in congenital syphilitics. A tabular view of the defects found in the 120 children is as follows:

The Three Types	Syphilitics	Non-Syphilitics
Speech	9	0
Vision	5	2
Hearing	3	3
Plural Defects in One Individual		
None	43	55
One Only	11	3
Two	2	2

From this table one might say that in the congenital syphilitic individuals there are more apt to be plural defects.

For the sake of comparing the *defects* in the mental processes these were divided into the four groups of receptivity, imagination, affectivity and thought. Receptivity was taken to include perception, elementary association, range of observation and discrimination. Imagination was taken to cover memory proper, analytical ability, learning ability, planning ability and imagination. Affectivity was taken to cover suggestibility, volition, concentrated attention and emotional instability. Thought was taken to cover reasoning, judgment, comprehension and apperception. These results are represented below:

DEFECTS IN MENTAL PROCESSES.

The Four Types	Syphilitics	Non-Syphilitics
Receptivity	25	16
Imagination	22	19
Affectivity	24	29
Thought	19	17
Plural Defects in One Individual		
None	12	12
One Only	15	21
Two	18	14
Three	9	10
Four	5	2
Five	1	1
	60	60

The results indicate that in the mental processes as in the special organs just considered, in the syphilitics there are more apt to be plural defects in one individual.

The *delinquencies* were treated under three groups, individual, property and society. Individual delinquencies were considered to be those of truancy, stubbornness, incorrigibility.

lying and sex. The property delinquencies were considered to be larceny, destruction, setting fires and breaking and entering. The society delinquencies were considered to be disorderly conduct, contentiousness, fighting, carrying concealed weapons, assault with intent to do bodily harm and minor offences. The results of this treatment are represented in the following table:

DELINQUENCIES.

The Three Types	Syphilitics	Non-Syphilitics
Individual	32	21
Property	13	15
Society	3	3
Plural Delinquencies in One Individual.		
None	24	32
One Only	18	18
Two	8	3
Three	7	4
Four	3	2
Five	0	1
	60	60

The same inference is apparent in the delinquencies as in the other defects, namely that the syphilitics are more apt to manifest plural delinquencies in one individual than are non-syphilitics.

If one looked over these results to note the instances where the syphilitics were inferior, equal or superior from the mental and social point of view to the non-syphilitics, one would find that there are twenty instances of inferiority, six instances of equality and six instances where the syphilitics are more favored. In summarizing, one could rightly say that in the 120 individuals under 15 years, all of them presenting acute social problems and all standing on the same ground except for this one factor of congenital syphilis, those that come in such a group present the greater social problems.

iii.

In many cases it is possible to outline a definite family pathography in regard to congenital syphilis. The picture before and after the syphilitic invasion is generally a contrast between normal mental development and under-development with early deterioration. For the sake of emphasizing this before and after picture of the mental development four families are taken from among the records of children looked up in Section III.

In the first family the father and mother represented normal development and intelligence to all appearances. The first child is a living male of 16 who is exceptionally bright. The second is a living female of 9, who is exceptionally bright. The third is a living female of 7, reported by her school teacher as being exceptionally bright. The fourth child is a living female of 6, who came after the infection. Her mental age is that of a 3-year-old child and in

the past two years she has grown progressively worse. The neighbors say she has changed in "character, disposition and mind," and her school teacher says she is as different from what she was as "dark is from light." The fifth child was a female that died at 9 months. The sixth child is a living male of 3 with characteristic physical ailments and slight retardation in mental development. The seventh child is a living female of 11-2 years, and the eighth child is a living male of 3 months. These latter two appear normal as yet.

In the second family the father and mother are normal physically and of average intelligence. The first child is a female of 12, who measured on the Binet 12, and on the Point Scale 15. She is reported from school as exceptionally bright. Then there came the infection, and this was followed by one miscarriage. The third child is a female of 11, who is feeble-minded, measuring on the Binet 8-1-5, and on the Point Scale 8.3. This birth was followed by another miscarriage.

In the third family the father suffers from alcoholic deterioration and tuberculosis, and the mother is apparently normal. The infection in this case was followed by a female now living at 10 years of age, who is mentally two years retarded and suffers from cerebrospinal syphilis. The second child is a living female of 7, who is one year retarded in mental development. The third is a female of 5 years, one year retarded and suffering from congenital syphilis. The fourth child is a living female of 3 years, apparently normal as yet.

In the fourth family the father is 62 and suffers from gonorrhea. The mother is 46 and has not been well since marriage. The infection was followed by a male child who died at 11 months of diphtheria. The second child was a male who died at 18 months of pneumonia and scarlet fever. The third child was a male who died at 22 years of tuberculosis. Throughout his life he suffered from convulsions. The fourth child was a male who died at 20 of pneumonia. The fifth child is a male living at 18 with juvenile general paresis and mental deterioration. The sixth child, a female, is living at 16 with cerebrospinal syphilis and mental deterioration. The seventh was a still-birth at 8 months. The eighth was a female child who died at 14 months with spinal meningitis and convulsions. This child was followed by a miscarriage at 3 months.

iv.

The results of this study can be set forth as follows:—

1. There is increasing authority for considering the endogenous psychoses and the psychoneuroses to be the last offshoots of luetic heredity.
2. The laboratory findings afford the best

classifications of congenital syphilis and there are six possible groups on this serological basis.

3. Of children under 15 years constituting social problems, the congenital syphilis constitute the more serious problems. Among them there are more cases of backwardness in school, there is more feeble-mindedness and retardation, there are more defects in the mental processes (with the one exception of affectivity), there are more delinquencies, there are more defects in vision, hearing, and speech. And if we consider the single individuals with one or more defects, then in the syphilis there are more individuals with plural defects in the mental processes, there are more individuals with plural delinquencies, and there are more individuals with plural defects in the two main sense-organs and in speech.

4. In families where the syphilitic infection makes its appearance the before and after picture in the mental development of the children is clearly delineated. In two families the earlier children were exceptionally bright in school. Then there came the syphilitic invasion and the following children are feeble-minded in early youth and show a rapid deterioration of mentality. In another family the infection was followed by two children who are victims of cerebrospinal syphilis and two children who appear normal as yet, but three of the four children are retarded in mental development, two at least two years, and one one year. In another family of nine children the infection was followed by miscarriages, still-births, and early deaths until today but two of the nine children are left, and one of these is a victim of general paresis with mental deterioration and the other a victim of cerebrospinal syphilis with deterioration.

We are indebted to Dr. H. C. Solomon for the determination of the syphilitic and non-syphilitic individuals and families.

VI.

DIAGNOSTIC VALUE OF LANGE'S GOLD SOL TEST. (BASED ON 500 EXAMINATIONS OF THE SPINAL FLUID.)

By HARRY C. SOLOMON, M.D., BOSTON.

Assistant Physician, Psychopathic Hospital;

HILMAR O. KOEFOD, B.S., BOSTON,

Intern, Psychopathic Hospital,

AND

EDWARD S. WELLES, B.S., BOSTON,

Intern, Psychopathic Hospital.

Three years have elapsed since Lange published his original communication on the colloidal gold test for cerebrospinal fluid. At this time he made a number of suggestions as to its

diagnostic value.^{2, 3} Several workers following him have confirmed many of his findings. This communication is a survey of the results obtained at the Psychopathic Hospital with this test during a little more than a year in the examination of the cerebrospinal fluids from 500 patients, a number of whom have had several punctures. One hundred and thirty-five of these fluids were reported in the *BOSTON MEDICAL AND SURGICAL JOURNAL*, December 10, 1914.¹³

We will not discuss the technic of the test as this will be found ably described in several of the articles,^{2, 3, 7, 8, 9, 10} the references to which are appended. It may be well, however, to call attention to some difficulties and precautions. At times it is with the utmost difficulty that a satisfactory solution is obtained. One prepares the agents as usual and yet the resulting solution is not as it should be. No reason is found for this, and after numerous tests in which no change in technic is made, a perfect solution is obtained. One must be careful in the selection of a solution, as certain solutions which look right will not give satisfactory results; that is, a solution may be too sensitive or not sensitive enough. Thus, an over-sensitive fluid will give strong reactions with fluids from apparently negative cases, and a too stable fluid will not give sufficiently strong reactions. In order to be certain of one's results, it is necessary to run controls with every new solution, using at least one known negative and one known strongly positive fluid; if this is not done one cannot feel confident of the results obtained.

Stated briefly the following diagnostic results have been claimed for the gold sol test:—

1. General paresis gives a typical reaction, the so-called "paretic" reaction.
2. Syphilitic cases give a reaction in low dilutions ranging from 1/10-1/320, called the "syphilitic zone."
3. Tabes and cerebrospinal syphilis give reactions in the syphilitic zone, but differing from the reaction given by general paresis in being weaker.
4. Tuberculous meningitis and brain tumor with inflammatory products in the fluid give reactions outside the "syphilitic zone," that is, in the higher dilutions.
5. Purulent meningitis gives a reaction differing from syphilitic meningitis.
6. The test will often give the only evidence of syphilitic involvement of the central nervous system in latent syphilis.
7. Fluids from normal patients or from patients having no inflammatory conditions of the central nervous system will give negative reactions.

The test is performed with ten dilutions of spinal fluid ranging from 1/10-1/5120 and the color change of the reagent varies from the

* Being S. B. I. Contribution whole number 127 (1915,30).
Bibliographical Note.—The previous contribution was by J. H. Bazeley and H. M. Anderson, entitled "Mental Features of Congenital Syphilis," *BOSTON MEDICAL AND SURGICAL JOURNAL*, Vol. cxxviii, No. 26, p. 952.

negative red through red-blue, blue-red, blue, lilac to colorless, depending on the amount of colloidal gold precipitated. These results may be plotted, using the dilutions for the abscissa and the color range for the ordinate. Or more simply, one may indicate the results by numbers, calling the negative red 0, the red-blue 1, the blue-red 2, the blue 3, the lilac 4, and the colorless 5, placing these on a horizontal, the ten divisions of which represent the ten dilutions.

Using this latter scheme, the "paretic reaction" would be represented as

5 5 5 5 4 3 1 0 0

That is to say, the reaction has gone to its full intensity in the tubes of lowest dilution, running through a number of dilutions and then disappearing. This reaction may run through a lesser or greater number of tubes, but in order to be accepted as "paretic" it must begin with its full intensity in the first tubes of the series.

The "syphilitic zone" includes the first five to six dilutions, that is the dilutions of 1/10 to 1/160 or 1/320. In tubes, cerebrospinal syphilis, etc., the reaction then should be something as follows:

1 2 4 4 2 1 0 0 0 0, or
3 3 3 2 1 0 0 0 0 0, or

it may show other types of reaction, the essential points being that the reaction occurs in the lower dilution but does not run to its maximum possible intensity in the first one or two tubes.

Tuberculous meningitis and brain tumors give a reaction in which the height of the curve is outside the "syphilitic zone."

0 0 0 0 0 1 3 3 1 0, or
0 0 1 2 3 4 4 3 2 0

An entirely negative reaction causes no color change throughout.

0 0 0 0 0 0 0 0 0 0

The reaction is due to the presence of abnormal albuminous material, or possibly the presence of an excessive amount of the normal. The test is based on the empirical fact that the colloidal gold may be used for qualitative albumen determinations, depending on differing reactions, according to dilutions.¹ The normal quantity and quality of cerebrospinal fluid albumen gives no reaction with the solution as used. The presence of a color change or positive reaction indicates a change in the albumen content. So in any case in which there is a variation from the normal content may be expected to give a reaction, and this reaction will depend rather on the quality of the albumen than on its quantity. Thus in the case of a purulent meningitis with enormous quantities of albumen, the reaction was but very slight and only in the higher dilutions, while in another case giving but a small excess of albumen but in a case of general paresis, the reaction was a typical paretic one. It is to be assumed then that various disease condi-

tions cause the formation of different kinds of albumens, that is, there is a different albumen in the fluid in tuberculous meningitis than in general paresis. If this is the basis of the test there is nothing *à priori* against several different diseases causing the same reaction.

It is our purpose to analyze the results of the tests of the 500 patients in the light of the above-mentioned contentions and to offer such criticisms and conclusions as seem warranted from the series. In a test of such an empirical nature this group is quite small, but as it is larger than any other we have been able to discover in the literature it may have some value. In each case here reported the diagnosis is that made after considering the various clinical symptoms and laboratory tests. In practically every instance, in addition to the gold sol test there is a blood serum Wassermann reaction, spinal fluid Wassermann reaction, cell count, Nonne-Apelt globulin test, and Mestrezat albumin test.

ANALYSIS OF RESULTS IN 500 CASES.

Group I. Clinical diagnosis. Syphilitic involvement of central nervous system, including general paresis, cerebrospinal syphilis, tabes dorsalis, juvenile cerebrospinal syphilitic disease, Erb's spinal paralysis, "paresis sine paresi."

1. General paresis 118 cases
 - (a) Typical "paretic curve" 114 "
 - (b) Atypical curve 4 "

In three of the four atypical curves the curve was a very close approximation of the "paretic," being of that type, 4443332211. In one it differed markedly, 2223310000, resembling the "cerebrospinal syphilis" curve.

In addition it is to be noted that slight changes have been found in the form of the curve in several cases punctured at intervals. This is quite frequent in cases receiving intravenous injections of salvarsan or intradural therapy,^{10, 15} but also occurs in others.

Percentage giving typical reaction.....	96.6%
Percentage giving almost typical reaction....	2.63%
Percentage giving atypical reaction.....	0.87%

2. Cerebrospinal syphilis..... 11 cases
 - (a) "Syphilitic zone—non-paretic". 8-9 "
 - (b) "Paretic curve"..... 1-2 "
 - (c) Negative reaction..... 1 "

One case which gave "syphilitic zone—non-paretic curve" on first examination gave the typical "paretic curve" on a second examination 4 months later. The "paretic curve" case gave this reaction on 4 successive fluids over a period of 3 weeks, but after several weeks' treatment with mercury presented an essentially negative fluid to the other tests and the following gold sol reaction: 0011100000. The case giving the negative gold sol reaction had other spinal fluid tests negative, but a positive blood serum Wassermann,—headache, ptosis, strabismus, diplopia.

3. Tabes dorsalis	5 cases
"Syphilitic zone"	4 "
"Paretic curve"	1 "
4. Juvenile cerebrospinal syphilitic disease	6 "
(a) "Paretic curve"	4 "
(b) "Syphilitic zone"	2 "
5. Erb's syphilitic spinal paralysis	1 "
(a) Syphilitic zone	1 "
6. "Paresis sine paresi"	4 "
(a) "Paretic curve"	3 "
(b) "Syphilitic zone"	1 "
7. Heubner's endarteritis (hemiplegia) ..	1 "
(a) "Syphilitic zone" (very slight reaction)	1 "
Total number of cases diagnosed syphilitic involvement of central nervous system	142
Total number showing reaction in "syphilitic zone"	141
Percentage showing reaction in "syphilitic zone"	99.29%

Group II. Cases giving paretic reaction but having negative Wassermann reactions in blood serum and spinal fluid.

Organic dementia	2
Cerebellar tumor (operation)	1
Korsakoff's psychosis	1
Unclassified (T. B. meningitis—not proved) ..	1
Tumor or T. B. meningitis	1
Multiple sclerosis	2
Total	8

Group III. Cases exclusive of syphilis of the central nervous system.

The figures at top of the columns represent the highest amount of color change, if any, produced by the fluid. Except where starred this reaction took place in the "syphilitic zone."

Percentage of cases having negative spinal fluid Wassermann reaction giving some reaction with the gold sol, 41.1%.

Percentage of positive serum cases, but negative spinal fluid,—

(a) giving a reaction with the gold sol ("1-5") ..	33.9
(b) " " "1" reaction	14.29
(c) " " "2" "	12.5
(d) " " "3" "	3.6
(e) " " "4" "	1.8
(f) " " "5" "	0.0

Percentage of cases with negative Wassermann reactions in blood serum and spinal fluid:

(a) giving a reaction with the gold sol ("1-5") ..	44.2
(b) " " "1" reaction	20.6
(c) " " "2" "	16.7
(d) " " "3" "	3.0
(e) " " "4" "	0.09
(f) " " "5" "	3.0

DISCUSSION OF THE RESULTS.

1. The "Paretic curve." Certainly one of the most valuable services that has been credited to the gold sol reaction is as an aid in differentiating general paresis and cerebrospinal syphilis. In certain cases the clinical signs and symptoms are amply sufficient for this differential, but there remains a group of cases in which the differentiation is impossible either from the clinical aspects of the case, the Wassermann reactions, cell count, globulin or albumin determinations. Such cases can be told apart only by the result of treatment (the cerebrospinal syphilis cases responding to treatment, the paretic cases not so doing), or by histopathological examination. As has been mentioned above, it has been claimed that the gold sol reaction will give this information. In examining the figures, however, it must be remembered that just this difficulty in diagnosis has been encountered in the cases reported, so that unless checked by autopsy, as these cases have not always been, one is not certain of the diagnosis. A further point to be considered is that, having accepted the statement that the gold sol will aid in this differential the clinician takes this reaction into consideration in making the diagnosis, and in a doubtful case will allow the result of the test to swing the diagnosis. Then later the laboratory man uses these diagnoses to prove the value of the tests. That the clinician has come to place much reliance on it, is shown by the statement

* NOTE.—The difference between the totals in Groups III and IV due to not having Wassermann reaction in serum of three cases.

of Adolf Meyer¹⁷ that the gold sol test is the basis of our conception of general paresis. Bearing this warning in mind, we find that of the 114 cases diagnosed as general paresis all but one, or 99.17%, give the "paretic reaction," so it seems safe to believe that in the vast majority of instances the cases which do not give this reaction will not prove to be paresis. But, unfortunately, the converse does not seem to be true, for cases other than paresis may give the typical "paretic reaction." Thus of the 11 cases diagnosed cerebrospinal syphilis there are two which give this reaction. On one the diagnosis was confirmed by the fluid tests becoming negative under treatment by injections of mercury salicylate, the other showing at one time the lighter reaction and later the full "paretic reaction." Eleven cases are too few to give percentages that have any value, but it is of some interest to note that one case which showed positive Wassermann reaction in serum and fluid, a pleocytosis of slightly more than 100, an excess of albumin and globulin and a gold reaction of 1110000000 came to autopsy three days later and was shown to be a typical cerebrospinal syphilis. (This case should be kept in mind as it is referred to below in discussing the "light reactions.")

Our series contains only 5 cases of tabes dorsalis. One of these again gave the paretic reaction, a finding that has been observed by others. It must be remembered that it is possible that this case may be developing tabo-paresis.

There are six cases of congenital syphilis, giving evidences in the fluid of inflammatory involvement of the central nervous system. Four of these give the "paretic reaction," two do not, but give a lighter reaction. Five of the six cases merit the diagnosis of juvenile paresis, while in the sixth, which did not give the paretic reaction, there might be some question whether the parenchymatous cerebral structures were affected. At any rate one case diagnosed juvenile paresis did not give the paretic reaction.

There are seven cases showing no other evidence of syphilis and having negative Wassermann reactions in both spinal fluid and blood serum, but which give the "paretic reaction." These seven cases to our minds are conclusive evidence that this reaction does not necessarily mean general paresis nor even syphilis. It may be noted that each of these seven was a case in which organic changes in the central nervous system were undoubtedly in progress, and six of them showed marked excess of albumin and globulin in the fluid.

From these 149 cases we feel justified in offering as a tentative conclusion that general paresis cases will in the vast majority of instances, especially if more than one sample of fluid is tested, give the "paretic curve," but that this curve may be given by the fluids from cases of syphilitic involvement of the central nervous system other than general paresis and also by

fluids from non-syphilitic cases, so that the "paretic curve" by itself is not sufficient evidence of paresis or even of syphilis. If, however, a fluid giving a positive Wassermann reaction does not give a "paretic curve" or one closely approximating it, it is strong presumptive evidence that the case is not one of general paresis. Thus the reaction has considerable value at times in the differentiation of certain cases of cerebrospinal syphilis and tabes dorsalis from general paresis.

The next point to be considered is the meaning of reactions in the "syphilitic zone," that is, reactions taking place in the first five or six tubes, or in the dilutions of 1/10 to 1/320. As has been seen, it is in these dilutions that the fluids from cases of cerebrospinal syphilis and tabes react, and it is outside of this zone in the higher dilutions that the fluids from purulent meningitis, tuberculous meningitis, brain tumor, etc., characteristically react, hence the assumption has been made that fluids reacting in the lower dilutions spelled syphilis in the subject. And as a certain percentage of the cases from which this reaction was obtained showed a positive Wassermann reaction in the blood, it was stated that this gold sol reaction in the "syphilitic zone" might indicate a syphilitic involvement of the central nervous system, and might be the only evidence of it. Thus the reaction of fluids from the Mongolian idiots in this zone has been offered as evidence that the condition is a result of syphilis.²⁰

Reference to Groups III and IV discloses about 40% of the cases having negative spinal fluid Wassermann tests showing reaction in this zone, and the percentage is as high in the cases whose blood serum reacted negatively as in those where it was positive. It is true that the reaction is not very strong in the majority, that is, most of the reactions only ran as high as "1" or "2." Due to the finding that so many fluids, which to the usual tests are negative, give this gold sol reaction, it has been held by some that this high reaction should not be considered. Thus Fleisch¹² found 50% of his supposedly normal fluids giving some reaction, so that he was prone to consider that these reactions should not be considered positive unless the reaction was "3." But as about 60% of the fluids which were expected to give entirely negative reactions did give such a negative reaction, it seems that the color changes, even though not very marked, do mean positive reactions. In support of this idea we find that in a fair percentage of these cases there is a very slight globulin test, or a small increase of albumin or both. In a few the sugar-content of the fluid varied considerably from the average. These findings seem to bespeak a not entirely negative spinal fluid. But more to the point in considering these light reactions is that many of the known inflammatory conditions give just this type. Thus the autopsied

case of cerebrospinal syphilis, mentioned above, although showing marked products of inflammation in the fluid, gave a lightest possible reaction. Tabes and cerebrospinal syphilis frequently give these light reactions, but finding other tests positive in these cases we do not hesitate to call this reaction positive. Also cases of purulent meningitis and tuberculous meningitis likewise may give the weak changes. So we believe that these small changes do have a significance, but that we do not know what it means. But it is further found that a small percentage of the negative cases give a fairly strong reaction in this zone. We therefore conclude that there is no justification for making a diagnosis of syphilis on account of a gold sol reaction in the lower dilutions unless supported by other tests. The term syphilitic zone we consider a misnomer.

Our cases of brain tumor (10) and tuberculous meningitis (5) are too few to give any important percentages. These two conditions, according to the literature, give reactions in higher dilutions than the syphilitic cases, although at times it is stated, the reaction may occur in the lower dilutions. Our results, as may be seen from the charts, bear this out fairly well, so that it may be stated that the fluids from cases of brain tumor or tuberculous meningitis will usually give reactions in higher dilutions than the syphilitic cases and thus a test offers a helpful point in differentiation.

For the remainder of the conditions examined, no conclusions of diagnostic value seem justified.

CONCLUSIONS.

1. Fluids from cases of general paresis will give a strong and fairly characteristic reaction, especially if more than one sample is tested, in the vast majority of cases.

2. Very rarely general paresis fluid will give a reaction weaker than the characteristic one.

3. Fluids from cases of syphilitic involvement of the central nervous system other than general paresis often give a weaker reaction than the paretic, but in a fairly high percentage of cases give the same reaction as the paretics.

4. Non-syphilitic cases may give the same reaction as the paretics; these cases are usually chronic inflammatory conditions of the central nervous system.

5. When a syphilitic fluid does not give the strong "paretic reaction" it is good presumptive evidence that the case is not general paresis, and this test offers a very valuable differential diagnostic aid between general paresis, tabes and cerebrospinal syphilis.

6. The term "syphilitic zone" is a misnomer, as non-syphilitic as well as syphilitic cases give

reactions in this zone, but no fluid of a case with syphilitic central nervous system disease has given a reaction out of this zone, so that negatively it may be used, and any fluid giving a reaction outside of this zone may be considered non-syphilitic.

7. Light reactions may occur without any evident significance, while a reaction of no greater strength may mean marked inflammatory reaction.

8. Tuberculous meningitis, brain tumor and purulent meningitis fluids characteristically, though not invariably, give reactions in higher dilutions than syphilitic fluids.

9. The unsupplemented gold sol test is insufficient evidence on which to make any diagnosis, but used in conjunction with the Wassermann reaction, chemical and cytological examinations, it offers much information aiding toward the differential diagnosis of general paresis, cerebrospinal syphilis, tabes dorsalis, brain tumor, tuberculous meningitis, purulent meningitis.

10. We believe that no cerebrospinal fluid examination is complete for clinical purposes without the gold sol test.

New Instrument.

A SALVARSAN APPARATUS.

BY CHAS. F. DENNY, M.D., ST. PAUL, MINN.

The accompanying sketch represents a useful and simple Salvarsan apparatus which is much used here.

It is reliable, practical, and simple, also it is easily constructed by any one at small cost.

Take a wide mouthed bottle of 360 c.c. capacity, fit it with a rubber stopper perforated for two glass tubes as you would a wash bottle.

Take 26 inches of rubber tubing to fit the glass tubes, cut it 18 inches from the end and make a glass joint with the smaller cut end of the tube.

The long glass tube reaches to the bottom of the bottle and is to be connected with the rubber tubing into the end of which the needle coupling is inserted.

The short glass tube is connected with a double bulb such as is used with a thermocautery.

It is now ready for use after the salvarsan solution is poured in the bottle.

The stopper is fastened down by a wire or strips of plaster over the cork and around the neck of the bottle.

After the needle is inserted into the vein and the coupling is made, a few squeezes of the bulb are all that is necessary to force it slowly and steadily into the vein.

Care is taken not to allow air to enter the vein at the end of the injection.

The sketch renders more detail unnecessary.

Society Reports.

THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

MEETING OF WEDNESDAY, MAY 5, 1915, AT 8 P. M.

The President, DR. JAMES C. WILSON, in the Chair.

CARDIOVASCULAR POISONS; THEIR METHODS AND RESULTS

DR. ROBERT N. WILLSON: To those who know the heart simply as a muscular pump, the function of which is to supply the various parts of the body with blood, the term cardiovascular poison will mean little more than a drug, which causes the heart to misbehave, or to functionate badly. It is no very recent discovery that if any human organ is overrich in its nervous supply, the heart is that one.

It is an exceedingly important item of knowledge that one of the main nervous distributions in the heart is subendocardial. Highly important also is an appreciation of the probability that the cardiac nervous structures enter in greater or less degree into the inception, and the discharge of each and all of the main functions of the heart. Of three groups of cardiovascular poisons, here briefly discussed, the first is decomposition of food products. These I believe constitute the causal factor in arterial changes and the hypertension contributing so actively to the cardiac disease of later years. A second class of cardiovascular poisons consists of microörganismal influences which make their attack from without. The infectious diseases approach without adequate warning, and the harm is accomplished before the danger is realized. Syphilis, tuberculosis, rheumatism so-called, and diphtheria illustrate fairly well the various forms of microörganismal invasion of the heart and vessels. Syphilis and tuberculosis begin with heredity and very frequently do we find the children of luetic or tuberculous parentage the subjects of myocardial or valvular defects. The tubercle bacillus and its toxin also furnish us with an invariably diseased heart. Regarding the acute rheumatic infection, we are in an uncertain and a transitional stage with respect even to its etiology. In diphtheria we experience nearly 100% of instances of myocardial involvement. The third class of cardiovascular poisons is that of tobacco and alcohol. Histories of two patients are cited illustrative of tobacco poisoning. It is my confident belief that between tobacco and the various forms of food toxemia can be divided the responsibility for the vast amount of arteriosclerosis not attributable to syphilis and old age. From the evidence secured in my own cases, as well as the more definite demonstration in the long sought human autopsy of Favarger, and the laboratory work of v. Otto, it seems fair to conclude that degenerative processes are at work in every tobacco poisoned heart. Alcohol is almost the twin of tobacco in its anesthetic and narcotic effect. We need not discuss its lack of claim to a food value. This lack has been demonstrated beyond all peradventure and accepted as a working principle in all of the foremost laboratories. We know that in small doses and in large, alcohol in continued use soon depresses and then paralyzes the vasomotor nerves. While we do not know that

alcohol produces arteriosclerosis, we know that tobacco does, and that the use of alcohol practically implies the craving for tobacco. Other excesses in food and venery are closely associated with alcoholism and the tobacco habit that tend equally toward sclerotic vessels and myocardial disease. It is impossible, therefore, either to indict alcohol upon the score of directly producing arteriosclerosis or to relieve it completely of either a direct contributory or indirect responsibility for much of the rapidly increasing cardio-vascular disease. It is only fair to exonerate the drug alcohol from contribution to the sclerotic total when used by the physician in therapeutic dosage, if there be any such thing. There is an abundance of reliable evidence to show that the administration of alcohol lowers the vital resistance to bacterial infections by diminishing the power of the human economy to marshal its phagocytes at will and to manufacture the antitoxins requisite to combat the infections which work mainly as toxemias. The only conceivable occasion on which the drug could assist in a grave toxemia would be in such an infection as typhoid fever, occurring in a strong, robust individual of high antitoxic resisting power, in whom there was a too wholesale destruction of bacteria in the tissues with danger that the patient may poison himself to death through the very process that usually works the cure. In the vast majority of typhoid patients, however, this danger is not present. There are few physicians approximating above or below forty years of age who feel that a place remains for alcohol in the pharmacopeia of the well read and conscientious physician, except as an emergency stimulant, and then only in minimal dosage, which does not mean a half ounce or an ounce at intervals of a few hours. The physiologic effect of alcohol is better comprehended by the lay public today than by the average medical man, judging by the tide sweeping over the country. A week ago 700 physicians of Pennsylvania stood for the right of a community to determine by vote whether its citizens should exchange their health for avoidable cardio-vascular disease. The next advance will be the ranging of the national medical body on the side of the disuse of a drug now recognized, in any dosage, to be a cardiovascular nerve and muscle poison, a tissue destroyer, and an economic harm. . . I have touched in turn upon the several forms of clinical and laboratory evidence for and against the use of alcohol in medicine. I have mentioned three series of experiments confirming Dixon's conclusion that the first action of alcohol is a stimulation of the heart, and for every statement I have made I have given ample clinical and laboratory evidence of investigation known and trusted as such by the entire medical world. A study of the cardiovascular poisons is altogether incomplete without the consideration of an excessive production of the internal secretions, but I have confined myself to the three groups nearest to the citizen and the general practitioner.

DISCUSSION.

DR. H. A. HARE: Sometimes in meetings of American associations I regret that the custom is not carried out which is so constantly adhered to in English medical societies, namely: to follow the habits of our brothers the lawyers, who, at least, in court, attack one another vigorously. Anything that I say tonight, it goes without saying, is not said with any intention to give offense. Dr. Will-

son under the title of a paper on heart disease has really read an attack on alcohol as a drug. If I may be pardoned for saying so, the first mistake in his paper is that of making sweeping statements without the slightest justification for many of them, and some of them in direct controversion to known laws of physiology and pathology. To state, for example, that in the early stage of the influence of alcohol this drug stimulates the circulation by stimulating the vagus is to show an entire ignorance of what every second year student in medicine knows,—that the function of the vagus is inhibitory and that in its action it decreases functional activity of the heart rather than increases it. When the statement is made that alcohol produces arteriosclerosis and arterial spasm, and in the same breath the assertion is made absolutely that alcohol depresses the entire vasomotor apparatus it is difficult to agree, for it is not easy to see how a drug can produce a rise of blood pressure at the same time that it is producing a lowering of blood pressure by depressing the vascular system in general. The reader of the paper does not seem to be familiar with what physiologists and pharmacologists recognize as the true physiological action of alcohol. So far as the circulatory action of alcohol is concerned, in moderate amounts it does not act as a stimulant or as a depressant, but it equalizes the circulation. I believe there is no drug that has physiological power, which, if wrongly used, will not also have the power to do harm. In a recent meeting of the County Medical Society a gentleman who read one of the papers said that alcohol was always contraindicated in tuberculosis. While such a statement is too sweeping to bear weight, published under certain circumstances it might do harm. While the harmfulness of alcohol is well known in miliary tuberculosis, in fibroid phthisis with cough interfering with digestion, the administration of alcohol is the administration of a food which is burnt up in the body, which lends energy to that body, which stimulates digestion, and which if given in the proper form may even help to expectorate the material which is in the cavities. What is needed, I take it, is the presentation before this College of a paper which recognizes that when alcohol is abused it does harm; when used rightly, it has a definite, specific, and often a very valuable place in medicine. This is true in diabetes mellitus in which disease, in certain cases, alcohol burnt up in the body possesses a distinct food value. The reader of the paper has gone one step further and made the dogmatic statement that *all*—I think he said *all*—researches show that alcohol decreases the ability of the blood to combat infection. I will be equally dogmatic—They don't do anything of the kind. On the contrary, there are researches that show that alcohol increases the ability of the body to protect itself in certain instances. Some time ago, I presented a paper before the Association of American Physicians in which I presented the results of a research to the effect that in typhoid fever and tuberculosis, alcohol in proper doses increases very materially the bacteriolytic action of the blood. The technic by which the studies were made was according to directions given by Dr. Simon Flexner. Upon one point Dr. Willson and I agree,—that the crusade in the profession which has been waged against alcohol has diminished the size of the dose that many physicians now give.

DR. H. C. WOOD: There are several loose expressions in Dr. Willson's paper which I do not think

should be allowed to go uncorrected. He speaks of the "cardiovascular action" of drugs. It is well-known that a drug may have one action upon the heart, and an opposite action upon the blood pressure. Because a drug lowers blood pressure is no proof that it depresses the heart, and vice versa. Pharmacologists always separate these two actions, and study the effect of the drug upon the heart as distinct from its effect upon the blood vessels. If he had made this distinction he would probably not have fallen into the error of comparing alcohol to nicotine in its physiological action. It is hard to imagine two drugs more widely different in physiological effect than alcohol and nicotine.

Dr. Willson in drawing his conclusions from the experiments quoted, fails to make sharp the distinction between the therapeutic, and the toxic dose of alcohol. He speaks of the secondary results of alcohol as if the depressant effect followed when therapeutic quantities were given; whereas, I understand that the depressant results are the effect of toxic doses. Dr. Willson quotes the experiments of Dr. Dixon, but neglects to say that Dixon reached the conclusion that alcohol acted as a food-stuff for the heart. It is a long time since I read Kochmann's paper, which he has also quoted, but the impression made upon my mind at that time was that he regarded alcohol in proper dosage as a stimulant to the heart muscle. I do not think there is any reliable scientific evidence that the secondary effect of small doses is a depressant action upon the heart muscle.

Dr. Willson, closing: I am by no means sorry to have my paper combated this evening. I am afforded an opportunity to reply to one or two misleading statements, far more "sweeping" and "irresponsible" than anything to be found in my paper. For instance, Dr. Hare ventured the assertion that I was guilty of ignorance of the first principles of cardiac physiology on the basis of my having made a statement (as claimed by him) that alcohol or any other drug stimulates the heart by stimulating the vagus nerve. What I actually did say, and that which I now repeat, was that alcohol causes a stimulation of the cardiac action through its depressant action upon the vagus nerve. There is no one, I imagine, who is not familiar with the fact that the action of the vagus on the heart is inhibitory. Dr. Hare by his remark would appear to lay himself open to the suspicion of possible ignorance with respect to the action of the sympathetic nerve when the controlling influence of the vagus is set aside. Again, I made no such statement as that alcohol produces arteriosclerosis. Indeed, I made absolutely the opposite statement, namely: that there exists no final evidence that alcohol does produce arteriosclerosis. I did show that the combination of tobacco with alcohol often results in the production of arteriosclerosis. I also took pains to refer to the fact that the combined action of the two drugs gives a different result from that of alcohol alone. Dr. Hare claims that the difference between the action of alcohol and tobacco lies in the fact that tobacco raises the diastolic, and lowers the systolic blood pressure, whereas alcohol lowers both in its secondary action. Dr. Hare is correct in his belief that the dominant action of alcohol is vasodilator after its first temporary splanchnic-constrictor influence, but he forgets the important fact that vasodilation also characterizes tobacco after its early vasoconstrictor action, and becomes its permanent influence. The evidence obtained from the action of both of these drugs is

to the effect that vasoconstriction and the elevation of blood pressure are not indispensable to the production of arterial disease. I was sorry to hear Dr. Hare revert to the fallacy that alcohol is a food in any true sense of word. In a recent meeting of the County Medical Society, Dr. A. E. Taylor showed in a most conclusive manner that alcohol is never a food in the true sense; and that to call it such shows an entire ignorance of the readily available laboratory findings. Dr. Taylor's statements represent the consensus of intelligent medical opinion on the subject. If in the discussion anyone has seemed to question the evidence I have submitted, such questioning is of the accuracy of the statements of investigators known and trusted by the entire medical world.

SERUM STUDIES IN PREGNANCY.

A Study of the Specificity of Ferments in Pregnancy and the Mechanism of the Abderhalden Reaction. 1. By Means of Local Skin Reactions. 2. By Proteotoxin Production in Vitro.

By DR. JOHN A. KOLMER

AND

DR. PHILIP F. WILLIAMS.

Aside from the probable clinical value of the methods devised by Abderhalden in the serum diagnosis of pregnancy and various pathological conditions, such as malignancy, tuberculosis, lesions of the nervous system and ductless glands, most interest concerns the question of the specificity of the ferments or antibodies concerned and the mechanism of their action. While Abderhalden and many of his pupils have claimed a high degree of specificity for the "protective ferments" and his pregnancy reaction, claiming from the beginning that errors of technic were largely responsible for the failure of others to obtain satisfactory results, the dialysis test as now conducted is not especially difficult and sufficient work has been done by other investigators who have carefully followed Abderhalden's technic to warrant the claim that other factors than those purely technical may be responsible for the divergent and non-specific results obtained.

SUMMARY OF PART I.

1. A *placentin* (No. 1) prepared by concentration of expressed placental juice, preserved with 1% glycerin and 0.5% tricresol and injected intracutaneously yielded skin reactions characterized by erythema, infiltration and pain in 87% of pregnant or recently delivered women, and in 66% of women who have borne children, but who were not pregnant at the time these tests were made. This extract also caused 20% of the men tested to react slightly.

2. When diluted 1 to 10 with normal salt solution this extract yielded 80% positive reactions among pregnant or recently delivered women, and 50% positive among women who had borne children.

3. A *placentin* (No. 4) prepared in the same manner as the first extract except that glycerin was not used in its preparation or preservation, yielded 40% positive reactions among pregnant or recently delivered women, and 14% positive reactions among women who had borne children. It is probable that

glycerin itself acts as an irritant, especially in the hypersensitive skin of pregnant women.

4. A *placentin* (No. 2) prepared from the residue resulting from the concentration of expressed placental juice yielded 55% positive reactions among women who were pregnant or recently delivered. This *placentin* produced slightly positive results in 20% of the men tested.

5. A glycerin extract (*placentin* No. 5) upon cutaneous inoculation yielded 50% positive reactions among pregnant and recently delivered women. Of several multiparous and nulliparous women tested, all reacted negatively.

6. Extracts of human male and female kidney (*nephrens*) prepared in the same manner as the *placentins* produced a number of positive reactions among pregnant, puerperal, multiparous and nulliparous women. The most marked reactions were observed with the extract of human female kidney.

SUMMARY OF PART II.

1. Proteotoxins are produced during the Abderhalden pregnancy reaction, which, when injected intracutaneously and intravenously into normal animals, produce local and general changes analogous to anaphylactic reactions.

2. Proteotoxins produced in a mixture of human pregnancy serum and human placenta are toxic for normal guinea pigs.

3. The ninhydrin test with dialysates and intracutaneous and intravenous injections of the sera in the Abderhalden reactions yielded fairly parallel indices of the degree of protein digestion and proteotoxin production.

4. The addition of various tissue substrates other than placenta to human pregnancy serum was followed occasionally by proteotoxin production, as shown by intracutaneous and intravenous tests with the serum, but except when a substrate of human kidney was used, the amount of proteotoxin produced was usually much less than that produced in mixtures of pregnancy serum and human placenta. Similar results were observed with inorganic substances, as kaolin, starch, and quartz.

5. The proteolytic ferments in healthy normal serum may produce small amounts of proteotoxins when tissue substrates are added and occasionally, and to less degree, with inorganic absorbents as kaolin and starch.

6. Complement in itself has no direct relation to the ferments in pregnancy serum. Inactivation of serum probably reduces its digestive power through destruction of normal proteolytic ferment and reactivation of a serum by means of the addition of serum complement increases its digestive power to a slight degree probably by reason of the addition of these normal ferments.

7. In pregnancy serum there are two sets of proteolytic ferments, normal and non-specific and specific ferments. The former may be released through absorption of the antiferment by means of various non-specific organic and inorganic substances, whereas, the latter are released through absorption of the antiferments by means of the specific protein antigen alone.

8. Our experiments suggest also that the protein matrix in the Abderhalden reaction is not only the protein of the serum, but also to some extent is that of the tissue substratum itself.

While we have naturally hesitated to report upon the local skin reactions in pregnant and puerperal

women until a relatively large number were studied, in view of the contradictory results obtained by others, we feel justified in concluding that the reactions were anaphylactic in nature and due to an anaphylatoxin produced by the action of general ferments upon a protein substrate. We do not believe at present that the reaction in the skin test for pregnancy possesses a practical value in diagnosis, certainly not among women who have borne children. According to experiments described in Part 2, pregnancy serum contains proteolytic ferments which, when rendered active, produce toxic substances capable of inducing local and general reactions analogous to those observed by Vaughan, Friedberger and others and regarded as anaphylactic in nature. Our experiments also suggest that in pregnancy serum there are two sets of proteolytic ferments, one composed of normal non-specific ferments and the second of more or less specific ferments. Our experiments are in accord with those of Jobling and Petersen, Plaut, Peifer, Bronfenbrenner and others to the extent that inorganic substances as kaolin are capable of releasing the normal tryptic activity of a serum probably through the absorption of antiferment followed by the digestion of serum protein. Our work indicates that this action is non-specific, and the result of the release of normal proteolytic ferments, whereas, the activity of the specific ferments in pregnancy serum is best in evidence in the presence of placental tissue.

Harvard Medical School.

RENAL PHYSIOLOGY AND PATHOLOGY.*

PHYSIOLOGY OF KIDNEY SECRETION—DR. E. G. MARTIN.

In hasty review of the anatomy of the kidney it is of importance to note that the afferent vessel of the tangled mass of capillaries, known as the glomerulus, is larger in lumen than the efferent vessel, hence, there is obviously an interference with the escape of fluid through a purely vascular channel. Furthermore, the cells lining the tubules suggest by their appearance and their rich blood supply that their function is secretory. This brings up a question which is better considered after we have reviewed the data of urinary secretion, on which there can be no doubt. The facts of importance are:

(1) Urine is more concentrated than the blood from which it is derived, and also presents striking differences in composition from that of the blood.

(2) The structure of the glomerulus affords a greatly increased "bed" for the flow of the blood through the capillary and, pressure being maintained by a small outlet, provides an ideal arrangement for filtration: i.e. a slow current under pressure with very thin containing walls. It is agreed by nearly all investigators (1) that the glomerulus acts as a filter by letting through water (a large amount of the water in the urine), and (2) that the more complex organic substances with larger molecules are not let through by filtration but are secreted; creatinin for example.

* Lectures at the Harvard Medical School on Dec. 10, 1915.

(3) In general the function of the kidney is to maintain the blood in standard condition, by means of selective qualitative and quantitative elimination. With the exception of the volatile constituents eliminated by the lungs and the few substances eliminated by the bowel and the skin, all of the qualitative and quantitative abnormalities of the blood must be dealt with through the kidneys.

Now the controversy in regard to kidney secretion is over the presence in the urine of substances of small molecular weight—one camp claiming that they filter through with the water in the glomerulus, the other camp believing that these substances are secreted in the tubules. Time prevents a thorough discussion of all the factors in the two theories, but as the secretion theory is most generally accepted we shall consider the evidence in its favor.

If, as Starling and the supporters of mechanical filtration believe, crystalloid (no colloids) substances are filtered through, then urine in the glomerulus should have the same concentration of crystalloids as the blood plasma. But we find in nature two occasions where the urine, as passed, has lower concentration than blood plasma: (1) After copious beer drinking. (2) In cases of salt hunger where, with diminished intake of salt, the urine falls below the blood in salt content. In order to explain the high concentration of some urines, the defenders of the mechanical theory presume marked absorptive function on the part of the tubules, but this assumption is made unlikely by Leschke's work in 1914, in which he demonstrated by microchemical means the presence of sodium chloride and sodium phosphate in the cells of the tubules and their absence in the glomeruli.

But what is the explanation for the secretion of urine? By what mechanism is secretion initiated or increased? We are expecting more and more in physiology to find chemical agencies at the bottom of problems, and giving less attention to purely nervous mechanisms as explanation for bodily changes. No secretory nerves have ever been satisfactorily demonstrated in the kidney: only vasomotor nerves have been shown. It is probable that secretion is activated by hormones. This theory is supported by the fact that a substance may be derived from the posterior lobe of the pituitary which will produce increased kidney action, and further by the recent work of Cow who has shown a diuretic substance in the cells of the jejunum.

The action of diuretics is explained by the hormone theory of secretion on the basis that any substance increasing the volume of the blood (saline diuretics) increases the amount of hormones passing through the kidney, and that certain chemical substances (cafein-type of diuretics) act as stimulators of hormone action or as simply an irritative chemical substance.

DR. F. G. MALLORY: When the pathologist is called upon to give a basis for the classification of renal disease, he must bear in mind certain elements in making the classification.

1. The Time Element. The line between what we shall call acute or what we shall say is subacute or chronic must be arbitrary. An acute lesion due to staphylococcus aureus may develop in three to four days, whereas it takes months for leprosy to develop its own type of acute lesion. And in subacute

nephritis the toxic form differs so largely from the infectious that the meaning of subacute is thrown into doubt. By the word "chronic," too, the pathologist may mean an old healed condition, or he may mean a recurrent, or perhaps, continuous one. Then it is evident that acute, subacute and chronic are not exact in meaning and are qualified by the condition which they attempt to describe.

2. Etiology is usually mentioned in kidney disease when it is known. Tuberculosis of the kidney is so spoken of, and the scarlet fever kidney is considered an adequate name for a distinct type of lesion.
3. The nature of the lesion, whether toxic or infectious, or a combination, is of considerable importance.
4. Anatomical distribution of lesions is used most consistently in pathological classification.

Commenting on various photo-micrographs which were then shown, Dr. Mallory called attention to the reason for the difference between a tubular nephritis due to corrosive sublimate and the ordinary tubular nephritis. It is due to the fact that in the case of the corrosive sublimate kidney a deposit of lime salts occurs on the necrosed cells in the tubule, and normal cell regeneration is rendered hopeless. Hence the failure of the kidney to recover adequate function. Often what is really acute tubular is called acute interstitial, because there is so much interstitial cell infiltration and proliferation. There is a characteristic tubular nephritis caused by argyrol injections flowing into the kidney structures. The numerous minute deposits of silver in the tubules produce an x-ray picture which looks pathological—and the surgeon removes what he should have left in.

Glomerulo-nephritis may be predominantly capsular or intracapillary—the pure capsular has not yet been seen by the speaker. The final condition in capsular nephritis is the obliteration of the glomerular structure by organization into ever constricting fibrous tissue. Vascular nephritis may show the same lesions as an infectious agent would produce. The glomeruli are shut off from circulation and the endothelial cells undergo fatty degeneration. Amyloid is the only condition that affects merely the connective tissue, and is a purely mechanical lesion due to the pressure of the amyloid as it is produced by the fibroblasts. Interstitial reactions are often seen in ascending infections and, resulting in a diffuse process, are mistaken for the arterio-sclerotic type. Two essential differences between infections and toxic lesions are worth remembering always: an infectious lesion tends to be focal and may be of a different age from other lesions in the same kidney, whereas a toxic lesion tends to be diffuse and of the same age as the lesions elsewhere.

DR. HENRY A. CHRISTIAN: The distinction brought out by Dr. Mallory between infections and toxic lesions fits with the clinical experience that although you may see many signs of renal involvement, the function may remain perfectly adequate on account of a local distribution of lesion. Also this distinction explains the serious character of toxic nephritis which we often underestimate. Hence, we come to a more moderate view that kidney function and other bodily signs and symptoms

form the best basis for estimation of the kidney condition.

The clinical classification of nephritis cannot be as minute as the pathological. Pure types are far from the rule even in pathology and clinically the picture is very frequently a mixed one.

(a) Acute nephritis can be described best not by any special classification but by mentioning the duration, when possible the cause, and the severity of the harmful agent as is shown clinically. Further than this you cannot go.

(b) In chronic nephritis the more cases are studied the more futile and inadequate does subdivision into classes become. There are groups of cases which can be separated into:

(1) Cases associated with oliguria, much edema and slight blood pressure. This group is the "chronic diffuse nephritis without induration" of some authors, or "chronic glomerulo nephritis," or "chronic parenchymatous nephritis."

(2) Cases associated with polyuria, and no edema except secondary to cardiac decompensation. This group is the chronic diffuse with induration, or chronic interstitial nephritis.

(1) Primary chronic interstitial nephritis has slow progress, with renal lesion uppermost and not so much emphasis on hypertension or cardiac involvement. The diagnosis is based on history rather than clinical study.

(2) Secondary type following attack of Group I nature, where picture changes over to sclerotic changes in the glomeruli and a shrunken kidney.

(3) A third division of chronic interstitial nephritis with induration is made by some, the arterio-sclerotic kidney, where renal involvement is probably secondary to primary process in the arteries.

The general symptoms of chronic nephritis are such that it is important to realize:

- (1) A great many patients arrive at coma and uremia without having any symptoms.
- (2) A second class of patients on learning that they have albuminuria, will consult a physician early while they feel well, and thus get adequate treatment.
- (3) Some patients show cardiac symptoms which, on investigation, prove to have a renal origin.

The symptoms of chronic nephritis are legion, and often confusingly like other entirely different conditions. A few should be mentioned: loss of strength and physical deterioration, failure of concentrative power and forgetfulness. Headaches usually in the morning, with or without high blood-pressure. Great tendency to increased nervous irritability. Tremor. Sleeplessness—ability to fall asleep but constant waking up almost immediately. Paresthesias and hyperesthesias and peripheral neu-

ritis. Some cases with hemi-, mono- or paraplegias. Transient aphasias. Bilateral or unilateral hemianopsia and scotomata—all transient. Albuminuric retinitis. Gastro-intestinal: loss of appetite, coated tongue, foul breath, sense of heaviness in abdomen, intestinal flatus, vomiting, intervals of constipation or diarrhea. Abdominal pain in epigastric or appendix region. Polyuria, frequency, suppression, oliguria. Paroxysmal dyspnea, especially nocturnal dyspnea of asthmatic type. Recurrent winter bronchitis in old people. Dry skin and itching, occasionally skin lesions of various type. Nose bleeds occasionally. Edema.

Most of the above symptoms are not associated with edema, and they may be of very gradual onset.

A. GREGG, A.B.

Book Reviews.

Studies in Bacillus Welchii. By J. P. SIMONDS.
New York: Rockefeller Institute for Medical Research. 1915.

This monograph, issued on September 27, 1915, as No. 5 of the series of the Rockefeller Institute for Medical Research, represents an exhaustive investigation by the author in the laboratory of preventive medicine and hygiene at the Harvard Medical School. It is concerned with a morphologic, cultural and biologic study of Welch's gas bacillus, especially with reference to its classification and its relation to diarrhea. Clinical investigations on this latter aspect by Dr. Karl Ten Broeck and Dr. Frank Garm Norbury, were published in the issue of the *JOURNAL* for August 19 (Vol. clxxiii, p. 280). The data of Dr. Simonds's researches are recorded in a series of seventeen tables in the text. He concludes that the Welch bacillus designates not a fixed species, but a closely related group of bacteria requiring further classification. As a tentative basis for such classification he suggests the ability of different strains to produce acid and gas or to sporulate in media containing inulin and glycerin. Dr. Simonds personally isolated and studied about 50 of these strains with reference to their cultural and biologic characteristics and their toxin producing and hemolyzing powers, and described a method for determining the number of spores of this organism in the stools of infants. He also made quantitative studies of a large number of cases of normal adults and infants, of adults and infants with diarrhea and of patients with pernicious anemia, and determined the relation of these organisms to fermentative processes, of which they may be regarded as a reasonably accurate index. The monograph closes with an elaborate bibliography of 476 titles on this subject.

Hand-Book of Obstetrics. By KEDARNATH DAS, M.D. With 376 illustrations. India: Butterworth and Company, Ltd. 1914.

Das has presented this subject in a very satisfactory manner. His treatment of the various obstetrical procedures follows in the main closely that of American authors. The illustrations, chiefly from other authors, are well chosen and credit is given in all cases to the original. The last few pages contain "Hints on Obstetric Surgery," which are most valuable not only to the beginner, but to the physician who thinks himself fully capable of undertaking major obstetric work.

War Surgery. By EDMOND DELORME, Médecin Inspecteur Général de L'Armée. Translated by H. DEMÉRIC, Surgeon to In-Patients. French Hospital, London. With illustrations. New York: Paul B. Hoeber. 1915.

The volume upon War Surgery, which was reviewed in the BOSTON MEDICAL AND SURGICAL JOURNAL of June 24, 1915, has appeared translated into very good English by H. De Méric. The size and general characteristics of the book remain as in the French edition. The plates are beginning to show a little the effects of wear and frequent reproductions.

As was said before, the book is an excellent compendium of a department of surgery, which is at present of extreme interest.

A Text-Book of Surgery. For Students and Practitioners. By GEORGE EMERSON BREWER, A.M., M.D., assisted by ADRIAN V. S. LAMBERT, M.D., and by members of the surgical teaching staff of Columbia University. Third and enlarged edition. Thoroughly revised and rewritten. Illustrated with 500 engravings in the text and 23 plates in colors and monochrome. Philadelphia and New York: Lea and Febiger. 1915.

The third edition of Brewer's well known Text-Book of Surgery appears as a well bound, well printed, well illustrated volume of one thousand pages. It is fundamentally changed from the previous editions, not only by its increase in size and by the addition of many new illustrations, but also by the fact that it is no longer the work of Dr. Brewer alone, but of seventeen members of the teaching staff of Columbia University. It may fairly be taken, therefore, as an authorized statement of what the College of Physicians and Surgeons of New York believes to be essential for its students in the subject of surgery.

The transition from a one-man book to a col-

laborative volume has been effectively accomplished. It is indeed remarkable that the book retains to so high a degree the unity which is associated essentially with a volume written by a single author; this happy fact is probably due in considerable measure to the work of Dr. Lambert as editor; at all events, it is a fact that increases considerably the value of the volume as a text-book for students.

Dr. Brewer has revised the chapters dealing with the face, neck, throat, chest, upper alimentary tract, liver, pancreas, kidneys and ureters. All the rest of the book is the work of the collaborators. Justifying the statement of the preface, the book is virtually a new one. In looking through the text, it is pleasant to find that no mention of wire is made in the description of the operation for suture of the patella; that the "operative treatment of fractures should not be employed unless a satisfactory reduction cannot be obtained and maintained by the closed method"; that the Whitman method of treatment of unimpacted fracture of the neck of the femur is advocated; that the summary of the operative indication in appendicitis is rational, but not rabid; and that the descriptions of the various methods of operative attack in general contain all essentials, but are exceptionally brief, concise and clear.

The lumière colored photographs deserve a special word of commendation, since they are exceptionally good. It is obvious that there are very great difficulties associated with the problem of maintaining a limit of one thousand pages for a complete surgical text-book. In spite of this fact, Dr. Brewer has succeeded in a very high degree in accomplishing his purpose of "presenting clearly every phase of Modern Surgery." The book is strongly recommended to students and practitioners.

Twilight Sleep. By ALFRED M. HELLMAN, B.A., M.D., F.A.C.S. New York: Paul B. Hoeber. 1915.

Hellman is a firm believer in twilight sleep, count of the use of twilight sleep abroad and in this country. He has summarized the more important articles on the subject, but has not included in the bibliography by any means all of the articles which have appeared, although he states the bibliography is complete to June, 1915.

Hellman is a firm believer in twilight sleep for he says in the final sentence of his book that "until some better and more easily manipulated treatment is devised the technic outlined will be the method of choice for alleviating the pains of childbirth."

There are many more typographical errors than should occur in such a small book, and one would have difficulty in finding in the *Index Medicus* the names of some of the authors as Hellman has them.

DOCTOR STRONG'S WORK IN SOUTH AMERICA.

IN the brilliancy of the work accomplished by Dr. Richard P. Strong last summer in the suppression of the epidemic of typhus fever in Serbia, and of his work four years ago, at the time of the epidemic of pneumonic plague in Manchuria, the medical profession, as well as the public, is likely to overlook the equal brilliancy of his work and that of his associates in South America in 1913. In that year Dr. Strong went as leader of the first expedition to South America of the Harvard School of Tropical Medicine. Associated with him in the personnel of this expedition were Dr. Ernest E. Tyzzer, assistant professor of pathology in the Harvard Medical School; Mr. Charles T. Brues, assistant professor of economic entomology in Harvard University; Dr. A. W. Sellards, assistant in tropical medicine at the Harvard Medical School; and Dr. J. C. Bastiaens, director of the

Municipal Laboratory of Hygiene, at Lima, Peru. The report of this expedition has recently been published in a remarkable volume* issued from the Harvard University Press and abundantly illustrated with original figures.

In the introductory chapter the purpose of the expedition is stated to have been the investigation of certain forms of tropical disease in South America, with the idea of collecting material to be used for the instruction of students in the various courses of the school. The itinerary of the expedition is outlined, which was first to Kingston, Jamaica, thence to Colon and Panama, and from the Canal Zone down the west coast of South America to Buenaventura, Colombia, and Guayaquil, Ecuador. Finally the expedition went to Lima, Peru, whence it returned to Boston. In this chapter also are stated the principal disease problems whose investigation was to be undertaken.

The succeeding chapters deal respectively with material obtained and the discoveries made with regard to the following diseases: oroya fever, verruga Peruviana, uta, and yellow fever. There are also valuable accounts of the entomological investigations made by the expedition at Mutucana, Surco and San Bartolomé, in Peru, on various organisms supposed to be associated with the transmission of verruga Peruviana; of sanitary conditions and of the principal diseases prevailing at Guayaquil; and of the linguatulida obtained from crocodiles in the rivers near this city. There is also an appendix of five minor entomological communications.

Particular emphasis and three-fourths of the space in the report are given to the studies of oroya fever and verruga Peruviana. The importance of these hitherto little known tropical diseases is pointed out, and their distribution, seasonal prevalence, clinical features, pathology and histopathology are considered in detail. There has been confusion in the past between these two diseases, whose distinctive etiology had not been determined. After studying the conditions of their existence in Peru, it was concluded by the expedition that the two are distinct diseases. Verruga Peruviana is shown by Dr. Strong and his associates, by experimental cultivation and inoculation in animals, to be due to a virus transmissible to animals by direct inoculation and producing in them definite lesions. Oroya fever, on the other hand, is shown to be

* Report of First Expedition to South America, 1913. Cambridge: Harvard University Press, 1915.

due to an organism, parasitic in the red blood corpuscles and the endothelial cells, and sufficiently distinct from the other hematozoa to be classed in a new genus. *Verruga Peruviana* is chiefly characterized by a skin eruption and is very rarely fatal; whereas oroya fever is characterized by pyrexia and by a rapid and pernicious anemia, resulting in extreme prostration and frequently in death. The clear clinical differentiation of these two diseases and the scientific experimental determination of their etiology constitute the principal contribution of this expedition to the science of tropical medicine. It is significantly noted in the introduction that the results obtained and the discoveries made by the expedition serve to emphasize the importance of sending to the tropics other expeditions for the investigation of other specific problems. In this instance the knowledge obtained has been secured at comparatively small cost.

A word of repeated commendation should be added for the original illustrations presented in the form of forty-eight full-page plates, many containing two or more figures and a number being colored. It needs hardly to be added that the credit for the successful carrying out of this expedition redounds not only to Dr. Strong and his associates, but to the Harvard Medical School and to the American medical profession.

THE PROFESSION OF MEDICINE.

THE Harvard Medical Alumni Association has recently published a book called "The Profession of Medicine," compiled and edited by Dr. Arthur B. Emmons, 2nd, director of the Appointment Bureau of the Harvard Medical School. The book is a study of the doings and opinions of ten classes of the Harvard Medical School, 1901 to 1910, and is intended to be a helpful guide to the prospective practitioner and to those interested in the education and preparation of medical students for their several callings in medicine. In making this inquiry it was decided to send a circular letter to the members of ten classes, approximately nine hundred men. These physicians had been out of the Medical School from three to thirteen years. Some, therefore, were just beginning to practice after hospital work, while others were well established. No name or identifying address was asked. The questions were ten in number. They

asked for the location and the population of the town or city chosen, amount of hospital work taken after graduation, whether in general practice, or specialty, laboratory, teaching, public health or special work, amount of money made in each successive year since leaving the School, and the per cent of work now paid for in full. They also asked for an opinion on the need of the community for general practitioners, specialists, surgeons, and public health officers, whether a premedical preparation should predominate in studies of general culture or natural science, what was lacking in the school course to fit the recipient for his particular work, and whether the practice of medicine had proved satisfactory or unsatisfactory.

Over one-third of the men answered, and their frank expressions of opinion are most interesting and illuminating. A feeling of great satisfaction and love for the career of medicine is expressed by many men in the profession, both because of the amount of good they are enabled to do in the world, and because of the intense interest of the work itself. Very few regret their choice of life work, although there are many complaints against the overcrowded condition of the profession, the competition with "quacks" and the small monetary reward to be gained from its pursuit. The replies to the question as to the branch of medicine practiced is a striking comment on the medicine of today. Only 36 men were in general practice solely, 134 were in general practice with a specialty, 142 in specialties only. Of the specialists, 90 practiced surgery, 28 medicine, 23 obstetrics, 23 laboratory work, 19 eye, ear, nose and throat and 36 teaching.

Many physicians consider the practice of medicine unsatisfactory from the standpoint of money-making. The expense of training, that is, the amount of time and living expenses, far overbalance the actual amount received from patients in the early years of practice. Some men rather cynically express themselves to the effect that the only satisfactory way of entering upon this career is to regard it as a philanthropy. The few men who appear to have entered it solely to gain the reward of gold regret their choice of the career. The general opinion is that the consciousness of satisfaction comes not from the earnings in money, but from the amount of good accomplished for which the medical profession gives the opportunity. The

average earnings of the class of 1901 range from \$866 for the first year to \$4680 for the thirteenth year; that of the class of 1910, \$1237 for the first year and \$1835 for the fourth year.

The hospital training received after graduating from medical school is regarded by many as the most valuable part of their entire training in medicine. Nearly every man who did not take a hospital internship either specifically mentions his deep regret or he emphasizes the need of those especial things which an internship furnishes, such as actual experience in handling patients, surgical technique, details of treatment, and sufficient clinical instruction. On the other hand, certain men point out the fact that their lack in the medical school along lines of general therapeutics was made up afterward in the hospital. As for pre-medical education, 120 graduates favored sciences, 110 the arts, and 70 both or equally.

In general, summarizing from the report, the following facts may be stated. Two hundred and twenty-five definitely state that the practice of medicine has proved satisfactory to them, sixteen that it has not. The life, especially in rural districts and small towns, is often very strenuous and seldom is it lucrative. This is usually compensated for by the devotion of patients to their doctor, much less felt in urban districts. Unreasonableness and ignorance on the part of patients are perhaps the most trying parts of practice and require a large measure of benevolent patience. To be a good general practitioner takes more brains, judgment and energy than to succeed in a specialty. Specialization requires more preparation and brings bigger and easier returns. It is not surprising, therefore, to find that but thirty-six men were doing general practice only, while one hundred and thirty-four were doing general practice with a specialty, which probably would lead them in a few years to limit their work to the specialty. One hundred and forty-two already were doing only special work. For this reason it can scarcely longer be said that the majority of the graduates of the Harvard Medical School must go into general practice, or that the chief aim of the Harvard Medical School must be to train the general practitioner. Rather must its aim be to train broadly men of versatile capacity to meet the changing requirements of the medical profession, whether these requirements are those of the general practice of medicine in a rural district or those of one of a group of spe-

cially trained experts in a larger community, or to teach, or to enter public health work, or to develop new fields of medical usefulness. The question of location is a vital one in the doctor's career. Most of the dissatisfaction with the practice of medicine is traceable, directly or indirectly, to overcrowding. There seems to be no method at present of intelligently distributing physicians according to the need. It has remained a question largely of individual fancy resulting in the crowding to large cities. Several men speak feelingly on the question of proper instruction in medical ethics and on this subject the public also often wonders. Specific mention is made of various evils, such as fee-splitting, lodge practice, quacks, and patent medicines. But the greatest danger of all to the individual and to the profession in general is commercialism.

RÉSUMÉ OF COMMUNICABLE DISEASE IN MASSACHUSETTS FOR NOVEMBER, 1915.

THE number of cases of communicable diseases reported to the Massachusetts Health Department during November varied slightly from the number reported during October. The total number of cases this month was 4574; last month 4547. The following diseases have decreased in number: anterior poliomyelitis, cerebrospinal meningitis, diphtheria, and typhoid fever. There was an increase in the number of cases of chicken pox, measles, scarlet fever and whooping cough.

The amount of tuberculosis reported is of interest. During November, 1914, 510 cases of all forms of this disease were notified, while in November, 1915, 601 cases were notified. This increase in cases in all probability is due to better reporting as a result of the operation of the tuberculosis dispensaries.

In comparison with the same month last year the total number of cases was larger. This increase was due largely to the variation in the number of cases of measles and the marked increase in the number of cases of whooping cough.

Aside from tuberculosis (which always causes the greatest number of deaths), the important causes of death were diphtheria, typhoid, whooping cough. Of these diseases, diphtheria with its 65 deaths is of vital interest. Notwithstanding the fact that we know the cause, modes of

transmission, and have an efficient cure, the great toll of deaths continues from this disease. The other two diseases of prime importance are whooping cough and typhoid fever. An analysis of the returns shows that whooping cough caused 23 deaths during November. When we reflect that there is almost three times as much whooping cough in this state this year as there was last, it requires little calculation to anticipate a large number of unnecessary deaths this year. While there were only five deaths during the month from measles this does not tell the whole story. The after-effects of this disease are very much more harmful than the disease itself. This applies also to scarlet fever.

While the total number of cases of diphtheria decreased, the disease is still prevalent in the following places: Springfield, Worcester, Southbridge, Marlborough, Cambridge, Saugus, Brockton, Billerica, Leominster, Fitchburg, Maynard and Lowell. In some of these places there has been no increase in the number of cases over last month. In fact, in some of them there has been a decrease. This is true of Fitchburg.

In typhoid fever the only important focus has been at Ashburnham. Here there was a sharp epidemic.

Measles shows a marked tendency to increase in the following places: Salem, Chelsea, and Taunton, while in Springfield it is holding its own. It is also present in considerable number in Holyoke, Lawrence, Saugus, Lynn and Brookline.

Whooping cough seems to be scattered over the whole state. The most important points of prevalence are: Springfield, Newton, Lawrence, Winthrop, Framingham, Northampton and Provincetown. In the last named place the disease has been present for a number of months and shows a tendency to increase.

Scarlet fever was present in more than the usual amount in Lynn, Brookline, Leominster, Fitchburg and North Attleborough.

During the month of November, the only epidemic of importance occurred at Ashburnham. Twenty-one cases of typhoid fever were reported between November 7th, and November 23rd. A careful investigation is being conducted by both the state district health officer and the engineering division. This outbreak presents some puzzling features, and at the present writing, the source of infection has not been determined. A detailed report of this epidemic will be published later.

During the month of November, three cases of anthrax were notified. Two of these were in Woburn and one in the city of Boston. Somerville reported one death during the month from actinomycosis.

MASSACHUSETTS GENERAL HOSPITAL CLINICAL SOCIETY.

THERE has recently been organized in Boston a new medical society, the Massachusetts General Hospital Clinical Society, the notice of whose meeting appears this week for the first time on the last page of the JOURNAL, and will appear there regularly hereafter. The purposes of this organization, whose membership is made up of the house staff of the hospital, are to present single interesting cases, groups of cases, historical sketches, pathologic specimens, x-ray studies, and thus to bring together the various services, interest them in one another's work, and encourage reciprocal assistance. The lack of correlation of studies and of scientific stimulus has long been felt among house officers, and it is hoped the new society may meet this want, and that the labor necessitated by it may be a distinct source of profit to individuals.

The meetings of the Massachusetts General Hospital Clinical Society are to be held fortnightly at 7.15 p.m., generally in the out-patient amphitheatre, and the visiting staff, the administration, physicians, surgeons, and students are cordially invited to attend. Meetings have already been held on Nov. 24, Dec. 1, and Dec. 13, with interesting and profitable programs. The attention of the profession is particularly called to this new and promising organization, to which the JOURNAL takes sincere pleasure in extending its cordial good wishes for success.

CRIMES!

MEDICAL NOTES.

INCREASED MORTALITY IN NEW YORK DUE TO HEART AND KIDNEY DISEASES.—According to the weekly report prepared by the New York Department of Health, there were, during the past week 182 more deaths in the city than during the corresponding week of last year. The heavier mortality from diseases of the heart and kidneys was responsible for most of the above increase, 399 deaths being attributed to these diseases during the past week,—an increase of 106 deaths over the corresponding week of last year. The Department of Health has repeatedly called attention to the increasing mortality from these diseases and has repeatedly urged, as the best safeguard against them, a yearly medical exami-

nation by the family physician. The onset of these diseases is usually so insidious that before the symptoms become sufficiently pronounced to compel one to consult a physician, the disease has often advanced too far to permit of its being cured or even held in check. During the past week there were 1520 deaths, with a rate of 13.66, as compared with 1338 deaths with a rate of 12.15 for the corresponding week of last year. A difference of 1.16 in the weekly rate is equivalent to an increase of 128 in the number of deaths. In other words, while there were actually 182 more deaths, 54 of these are to be accounted for by the increase in the population. The death rate for the first 50 weeks of 1915 is 13.52, as compared with 13.66 for the first 50 weeks of 1914.

THE HOSPITAL STEAMSHIP "STRATHCONA."—The Wilfred T. Grenfell Association in reporting the work of its hospital steamship *Strathcona* from June 27, 1915, to September 27, 1915, states that a total of 958 out-patients were treated, and 27 in-patients. Of the out-patients, 115 had diseases of alimentation and 100 beri-beri, caused by the lack of variety in the diet of the poor fishing people to whom the hospital ministers. During the summer the boat had steamed 2250 miles; towed home (St. Anthony, Northern Newfoundland) five barge loads of wood; twice went to Lewisporte, (Newfoundland) to meet the train; visited all hospital stations: Indian Harbor, Harrington, Battle Harbor, Spotted Islands, Forteau, Paul's River, (Labrador), St. Anthony, Piley's Island, (Northern Newfoundland), and went to Twillingate to start another hospital.

AMERICAN ASSOCIATION FOR CLINICAL RESEARCH.—The annual meeting of the American Association for Clinical Research was held recently in Philadelphia. The following officers were elected for the ensuing year. President, Dr. Coleman of New York City, vice presidents, Dr. William B. Snow of New York City and Dr. Leon T. Ashcraft of Philadelphia, permanent secretary, Dr. James Kraus of Boston.

UNIVERSITY OF ILLINOIS.—It is announced that a new building is to be erected in Chicago for the clinical courses of the University of Illinois Medical School. Only one wing will be built at present at an initial cost of about \$100,000. The remainder of the building is to be added later as the demand for room increases.

EUROPEAN WAR NOTES.

MASSACHUSETTS RED CROSS SURGEONS IN ENGLAND.—In a recent issue of the London *Lancet* has appeared the following editorial account of a farewell luncheon given in London on October 13, by Sir William Osler to Dr. Howard Beal on the occasion of the completion of the latter's service as chief surgeon of the American Women's War Hospital at Paignton, Devonshire.

"Dr. Beal came over with the first American Red Cross units in September, 1914. The two units, then allotted to England, consisted each of three surgeons and twelve nurses; one unit was sent at once to Paignton; the other was for a time attached to Haslar Naval Hospital, but afterwards it also went to Paignton, and the hospital there then had a staff of six surgeons and twenty-four nurses, with an equal number of British and Australian nurses. Later on Dr. Crumley, of the Mayo Clinic, was attached as pathologist and bacteriologist. Sir William Osler proposed a composite toast to the American women in England who had achieved a fine piece of organizing work at Paignton, to the American Red Cross which had supplied the staff, and to Dr. Beal. Sir Alfred Keogh bore testimony to the admirable work done by the American Red Cross at Paignton, and by the Harvard and other units in France. In the name of the R.A.M.C., he thanked Dr. Beal and the American women in England, who, headed by Mrs. Harcourt and Lady Randolph Churchill, had made the enterprise possible. Dr. Beal gave some particulars of the hospital, stating that it now possessed 250 beds, with 20 others in an isolation block. During the year which had just been completed it had treated over 1900 patients with so much good fortune that it had had to record only five deaths."

Dr. D. Pearce Penhallow of Boston, the successor of Dr. Beal as chief surgeon of the hospital, has recently sent to the JOURNAL an analyzed report of the first one thousand of these cases treated there, representing the discharges from October 1, 1914, to March 14, 1915.

"Of this number 785 cases were surgical, 520 traumatic, and 265 non-traumatic. Of the traumatism 445 were wounds, the remainder mostly contusions and sprains. 254 wounds were infected, but only 2 with tetanus, both of which recovered, and none with the gas bacillus. Sixty wounds contained foreign bodies, requiring 51 operations for their removal. There were 115 fractures—7 of the skull, 3 of the jaw, 7 of the clavicle, scapula, or ribs, and 98 of the extremities. Of other complications, hemothorax occurred 12 times and aneurysm once. A total of 179 operations were performed, only 19 amputations among them, of which all but 4 preceded admission. Of non-traumatic surgical conditions, frost-bite headed the list with 144, and defective teeth came second with 21. Amongst 301 medical conditions, only 60 were of infections, endocarditis 19, dysentery 17, rheumatic fever 11. Of non-infections conditions, bronchitis and myalgia were much the most frequent. Turning to the results of treatment, cure was recorded in 63 per cent. of the surgical and 60 per cent. of the medical cases, improvement in 35 per cent. and 32 per cent., respectively. Only 3 patients died. The average time off duty before admission was 11.4 days and of stay in the hospital 22.8 days. Only 3:

were invalided out of service, and 54 transferred to other hospitals. The report deserves careful scrutiny, and is to be followed shortly by one on the second 1000."

WAR RELIEF FUNDS.—On Dec. 18 the totals of the principal New England relief funds for the European War reached the following amounts:

Red Cross Fund	\$142,298.92
Belgian Fund	73,023.63
Serbian Fund	58,042.07
Allied Fund	43,975.80
British Fund	41,020.72
French Fund	30,413.76
Armenian Fund	25,309.65
Surgical Dressings Fund	15,211.00
Italian Fund	13,549.69
LaFayette Fund	13,395.99
Polish Fund	9,611.12

BOSTON AND NEW ENGLAND.

THE WEEK'S DEATH-RATE IN BOSTON.—During the week ending December 18 there were 255 deaths reported, with a rate of 18.27 per 1000 population as compared with 264 and a rate of 19.12 for the corresponding week of last year.

A notable difference was a total of 14 deaths from pulmonary tuberculosis, against 24 last year.

There were 43 deaths under one year, as compared with 59 last year, and 83 deaths over 60 years of age, against 67 last year.

Total deaths reported in 50 weeks from January 2 to December 18 were 11,368, against 11,344 for the corresponding period in 1914.

Deaths under one year reported in the same period were 1927, against 1919 for the corresponding period in 1914.

During the week the number of cases of principal reportable diseases were: Diphtheria, 59; scarlet fever, 48; measles, 53; typhoid fever, 0; whooping cough, 42; tuberculosis, 52.

Included in the above were the following cases of non-residents: diphtheria, 9; scarlet fever 9; tuberculosis, 4.

Total deaths from these diseases were: diphtheria, 4; tuberculosis, 14; whooping cough, 5.

Included in the above were the following deaths of non-residents: diphtheria 2, tuberculosis, 2.

Only three cases of typhoid fever have been reported during the past three weeks in this city, which is the lowest morbidity record on this disease since typhoid fever was made a reportable disease, namely, 1881.

HOSPITAL BEQUESTS.—The will of the late Mrs. John E. Hudson which was filed in the Suffolk Probate Court on December 10, contains bequests of \$5000 each to the Boston Home for Incurables and the Boston Nursery for Blind Babies, and creates the Industrial School for Crippled and Deformed Children as residuary estate.

The will of the late Edward E. Taylor, filed on December 15 in the Suffolk Probate Office,

contains a bequest of \$10,000 to the Laconia (N. H.) Hospital; a bequest of \$2000 to the Florence Crittenden Home; and a bequest of \$1000 to the Boston Floating Hospital.

A SECOND CASE OF LEPROSY.—A second case of leprosy discovered in Boston recently proved to be an old sailor, about seventy-two years of age. He has followed the sea for many years and believes that his present illness was contracted while visiting Asiatic ports. Upon application to the Massachusetts General Hospital for treatment the nature of his disease was discovered. He was sent to the Southampton Street detention hospital and will later be taken to Penikese Island.

FREE WASSERMANN TESTS.—Beginning with January, 1916, the Bacteriological Laboratory of the Boston Health Department will be prepared to examine blood specimens by the Wassermann test for syphilis. Tests will be made each Tuesday, Wednesday, Thursday and Friday. Patients for whom the test is requested should be sent to the Laboratory, Room 1101, City Hall Annex, where the blood specimens will be taken. History blanks will be mailed to any Boston physician on request, and each patient appearing at the laboratory must present one of these, carefully filled out and signed by his attending physician. The Laboratory will be prepared to receive these patients and to collect the blood specimens on Mondays, Tuesdays, Wednesdays and Thursdays, from 2 to 4 p.m. only. Specimens will not be collected at any other time, nor will they be collected from patients coming without a carefully prepared history card. The data required are as follows:

* Patient's name; age; sex; patient's address; civil condition; married, single, widowed; provisional diagnosis; syphilis acquired or congenital; active lesions; stage, (primary, secondary, tertiary); antisyphilitic treatment, (number doses salvarsan, number doses neo salvarsan, mercury pills, number months, number mercury injections); present treatment; physician's name; physician's address.

This test, like all laboratory tests furnished by the department, is without cost to physician or patient.

GIFT TO BOSTON DISPENSARY.—At a recent monthly meeting of the board of managers of the Boston Dispensary, a gift of \$5000 was announced from Mr. Shepard Brooks. During the month of November a total of 10,472 treatments was given at the Dispensary of which 9593 were at the morning clinics and 879 at the evening clinics.

MASSACHUSETTS SURGICAL AND GYNECOLOGICAL SOCIETY.—The annual meeting and dinner of the Massachusetts Surgical and Gynecological Society were held in Boston on December 8. At the afternoon session under the chairmanship of the

*Initials in full will be accepted instead of name and address.

retiring president, Dr. Charles T. Howard of Boston, the following papers were presented:

Dr. Dewitt G. Wilcox of Boston, "The Treatment of Pelvic Adhesions"; Dr. Ralph A. Stewart of New York, "A Plea for Better Records in Fractures"; Dr. G. Forrest Martin of Lowell, "Some Phases of Surgery of the Lungs," and Dr. Walter G. Crump of New York, "Surgical Aspects of the Cancer Problem."

At the close of the session the following officers were elected for the ensuing year: president, Dr. H. O. Spalding of Westboro; vice president, Dr. Ralph C. Wiggan of Cambridge; secretary, Dr. Harry J. Lee of Boston and treasurer, Dr. C. Y. Wentworth of Newton Highlands.

Obituary.

EDWARD LIVINGSTON TRUDEAU, M.D.

IN the death of Dr. Edward Livingston Trudeau, not only the medical profession, but the world at large, has suffered a loss which it is quite impossible to measure or express in words.

Edward Livingston Trudeau was born in New York City in 1848. He died November 15, 1915, in his 68th year. His parents were both of French descent. As a boy, he grew up on his father's plantation near New Orleans. At the age of eighteen, he returned to the city of his birth intending to enter the United States Navy. His elder brother, however, at that time was stricken with tuberculosis and died within six months. Up to the hour of his death, he was attended by his younger brother, who thus for the first time came in contact with the disease which in later years he fought so long and well.

He entered Columbia University, and later the College of Physicians and Surgeons in New York, from which he graduated in 1871. He entered practice in the city and in the same year married Charlotte Beare. Of their four children, three died: one in infancy at Paul Smith's, another daughter, Charlotte, in 1893, and later Dr. Edward L. Trudeau, Jr. The death of the latter was a terrible blow to his father, who had hoped that the son who bore his name would also carry on his work.

Dr. Trudeau remained in practice in New York City only two years when he began to show symptoms of tuberculosis. His condition was considered a most serious one, and in the minds of his most intimate advisers, he was thought to have but a small chance of living more than six months or a year. Dr. Trudeau, himself, however, felt differently. He determined to go to the Adirondacks which he loved, and in this same year, with his wife, he took up his abode at Paul Smith's, then forty miles from the nearest railway. As soon as he arrived, he be-

gan to improve. He loved the mountains, and had an unbounded faith in the tonic properties of Adirondack air.

At Paul Smith's, he met Dr. Alfred L. Loomis, of New York. The elder physician had long held what were considered most radical ideas concerning the treatment of consumption and had been anxious to give his theories a fair trial. In Dr. Trudeau's case, he met his first opportunity to do this. During the winter of 1873 at Saranac Lake, Dr. Trudeau's health and vigor continued to improve so that in the next year he decided to venture abroad again.

He went to St. Paul, Minnesota, and after a year of busy practice, mostly indoors, again relapsed. He felt that which has been remarked in thousands of other patients who have come to the Adirondacks and gone away again—"the call of Saranac." Since that day, Saranac Lake and Paul Smith's have been between them the home of Dr. E. L. Trudeau.

As before, he was very ill, and hardly fit to take the long journey in a sleigh from Ausable Fork through the wilderness to Paul Smith's. Once again, however, the magic of Adirondack air performed the great miracle and Dr. Trudeau again recovered and his strength increased. He developed considerable practice both among the local residents and the summer visitors, and in 1877 he definitely took up his abode in Saranac Lake. Many of the patients whom Dr. Loomis had sent him, as well as those who had come to him voluntarily, went with him to Saranac Lake.

In 1882, the world was stirred by the discovery of the tubercle bacillus by Robert Koch of Berlin. This was Dr. Trudeau's inspiration to scientific research. Despite his enormous handicaps, he at once entered this new field of work. In 1884, with the advice and encouragement of Dr. Loomis, the first cottage of that which was in due time to become a beautiful sanitarium village,—Trudeau, N. Y., one and a half miles from Saranac Lake,—was erected on the side of Mount Pisgah. This little cottage represented the beginning of a great movement, the influence of which has been felt all over the United States and Canada. There are doubtless over four hundred sanatoria for the treatment of tuberculosis in this country alone that owe their inception directly or indirectly to the influence of Dr. Trudeau and the Adirondack Cottage Sanitarium.

Today, the Adirondack Cottage Sanitarium is a million dollar institution; yet each year it is run at a loss which has to be made up by the generosity of such individuals as have means and are willing to share them for a great cause. The arduous burden of making up this deficit has been borne by Dr. Trudeau despite his physical handicaps. He, himself, has refused to draw any salary as president of the institution.

Today, the Sanitarium at Saranac Lake is recognized as one of the greatest health centers on the American continent for the treatment and cure of tuberculosis. This and the Saranac Lake Laboratory are standing monuments to the greatness of this man.

Among the honors that have been conferred upon him are Master of Science, Columbia University, 1889; Honorary Fellow of the Phipps Institute, 1903; LL.D., McGill University, 1904; and LL.D., University of Pennsylvania, 1913.

In 1910, Dr. Trudeau was president of the Eighth Congress of American Physicians and Surgeons, held at Washington, D.C. He addressed the Congress on "The Value of Optimism in Medicine." The following paragraphs from this address in Dr. Trudeau's own words express better than anything else his own philosophy in life:

"Optimism is the one thing that is within the reach of all of us, no matter how meagre our intellectual equipment, how unpromising our outlook at the start, or how obscure and limited our careers may be.

"It was about my only asset when I built my first little sanitarium on a remote hillside in an uninhabited and inaccessible region. Viewed from the pessimist's standpoint, that little cottage as an instrument of any importance in the warfare against tuberculosis must have appeared as a most absurd and monumental folly.

"Optimism made me indifferent to neglect and opposition and blind to obstacles of all kinds during the long years of struggle before the value of sanitarium treatment became generally recognized. It enabled me to undertake the culture of the tubercle bacillus and delve in the complex problems of infection and artificial immunization, though I had no knowledge whatever of bacteriology, no laboratory, no apparatus or books.

"Let us not, therefore, quench the faith nor turn from the vision which, whether we own it or not, we carry as Stevenson's lantern bearers their lanterns, hidden from the outer world, and thus inspired, many will reach the goal; and if for the most of us our achievements inevitably must fall short of our ideals, if when age and infirmity overtake us 'we come not within sight of the castle of our dreams,' nevertheless all will be well with us; for, as Stevenson rightly tells us, 'to travel hopefully is better than to arrive and the true success is in labor.'"

To any one who knew him well, Dr. Trudeau presented a varying front. One of the greatest optimists that ever lived, he could now and then be one of the greatest pessimists. His temperament was distinctly French. The marvelous thing is that through all the sufferings of his latter years he could keep up his courage and cheerfulness as he did.

During his latter years, when for the greater part of the time he was confined closely to his

bed, he continued to be a constant source of inspiration to physicians who were fortunate enough to come into contact with him, to friends who had their own burdens to bear, and to patients from all over the world. He has preached the gospel of courage and faith in the eternal goodness of things. He was a friend to all the world, and all the world was a friend to him. No man ever laid down his burden more deserving of rest and the respect of his fellow men.

Miscellany.

ADVANCE IN COST OF DRUGS.

DURING the past month the increase in the price of drugs, which has been noted since the outbreak of the European War, continued its steady progress with regard to all important drugs, with the exception of quinine. Report from New York on November 30 makes the following statements on this subject:

"Most prominent among the price fluctuations in the list of fine medicinal drugs has been a fresh upward movement amounting to \$1.00 a pound in gum, powdered and granular opium. This advance was based on the virtual cessation of all shipments from Macedonia and Turkey, as well as shrinkage in local supplies and continued demand from abroad for all opiates. According to statistics just released by the Government, opium stocks in the United States are shrinking at the rate of close to \$90,000 worth a month. The stock of opium containing 90% of morphia and over in our bonded warehouses on October 1, 1915, amounted to but 47,189 pounds of the value of \$205,680, comparing with 67,687 pounds of the value of \$293,658 on September 1, 1915, 92,997 pounds of the value of \$394,088 on July 1, 1915. There has been no reflection of the additional advance in prices for opium thus far in morphine or codeine, but a much stronger undertone pervades the market, as foreign demand is reaching much larger proportions. Not only is the demand from Europe steadily on the increase, but a demand from Japan has sprung up here of late.

"Bromide preparations have continued unusually scarce in the local market, prices having been maintained at \$5 to \$6 a pound in second hands. All tests of acetic acid from 28% to 99½% glacial have scored sharp advances following an uplift of 50 cents per hundredweight in acetate of lime to a basis of \$5 to \$5.05 per 100 pounds.

"Russian cantharides have scored another sharp advance to \$5 a pound for powdered, while Chinese powdered cantharides have advanced 20 cents and are now being held at \$1.70 a pound, owing to a virtual exhaustion of the

supplies of whole. U.S.P. lac sulphur has risen to 20½ and 21 cents a pound on declaration of an embargo on shipments from Great Britain. South American balsam copaiba is 5 cents higher, at 45 cents per pound; balsam peru has advanced to \$4.75 and \$5; American saffron flowers to 75 cents a pound; Valencia saffron to \$11.25 and \$11.50; true liquid stryax to 45 cents a pound; oil of cloves to \$1.37½, and \$1.42½; bergamot oil to \$3.50; oil of cassia to \$1; juniper berries oil to \$3 and \$4; natural mustard oil to \$14; and artificial to \$9.50; oil of nutmegs to 90 and 95 cents; domestic peppermint oil in bottles to \$2.60 and \$2.65, and oil of patchouli to \$7.50 and \$7.75 a pound.

"So far as carbolic acid is concerned, it is notable that offers during the past three days have been made more freely around \$1.75 a pound basis in drums, and \$1.90 basis a pound in pound bottles. Production of benzol and carbolic acid have both been brought up to their maximum in the United States, according to leading representatives of the manufacturers. The high level for spot goods is maintained owing to the fact that the explosive manufactures are still taking the bulk of the output.

"Advances in the general list of the Far East drug and chemical products have also been quite general, the most important uplifts having occurred in such natural dye products as gambier, cutch, indigo, nutgalls and turmeric. Spot Aleppy turmeric has practically disappeared from the market. Tapioca, all the grades of cardamom seeds, nux vomica, gum assafetida, mastic, arabic, copal euphorbium, belladonna root, citronella and sandalwood oils, buchu, cannabis-indica, coca, senna and thyme leaves and Levant wormseed have all shown a stiffening tendency of late. The sales of cassias alone in this market have amounted to more than 10,000 pounds, and the same reason for the elevation of prices holds good; to wit, poor shipping facilities and neglect of crops in the primary markets.

"A sensational advance in prices asked for quinine salts was recorded the latter part of October. An advance in the asking price of second hands to \$2.50 and \$2.75 an ounce was the highest figure ever established for quinine since the Civil War. The effect of the sharp advance in prices asked for outside lots was to choke off the demand from Europe, as well as to restrict the inquiries from domestic consumers to such quantities as they would require for their own immediate needs.

"In early November, the British Government, taking cognizance of the sharp reduction in the stocks in London and all other centres, placed quinine on its list of prohibited exports in order to prevent further depletion of its own supplies. Contrary to general expectations, the vital effect of the cutting off of London as a basis for supply of foreign quinine did not result in any fresh flurry in the article. The market in second hands in New York, on the other hand, under-

went a serious reversal, prices dropped to \$1.50 an ounce, but even at this figure the margin over makers' prices was still attractive. In view of the fact, however, that the United States was dependent upon its own production, which is less than 1,500,000 ounces, or only one-half as much quinine sulphate as is annually imported, the prospects for the resumption of normal figures for quinine while the war in Europe continued were regarded as remote.

"Imports of quinine sulphate and all salts and alkaloids of cinchona bark in the first nine months of 1915 to October 1 totalled only 657,611 ounces of the valuation of \$165,247, which compares with 2,069,370 ounces of the value of \$471,318 in the corresponding period in 1914, and 2,565,850 ounces of the value of \$479,760 in 1913. The imports of cinchona bark during the same nine months totalled 3,073,307 pounds of the value of \$453,669, comparing with 3,236,785 pounds of the value of \$438,403 in the same time, 1914, and 2,284,378 pounds of the value of \$479,760 in 1913. The relatively small imports of sulphate in 1915 indicate that the bulk of the quinine consumed here during the past year was manufactured by domestic makers."

THE DOG AS A CARRIER OF DISEASE TO STOCK.

The dog in the country is a useful and pleasant adjunct to the farm, if he be properly controlled and cared for, but when neglected, may readily become a carrier of disease to stock, in addition to gaining opportunity to kill sheep and destroy gardens and other property. Dog ordinances, as a general rule, have been intended chiefly to curb the dog's power of doing harm by attacking, biting, killing or running sheep or stock. The part that he plays as a carrier of diseases to animals only recently has been recognized, according to the zoologists of the Department of Agriculture, who believe that when this is better understood, rural ordinances and laws which lessen this danger will gain the support of the community.

Of the diseases carried to stock by dogs, the foot-and-mouth disease is probably of the greatest interest at this time. In this case the dog acts as a mechanical carrier of infection. The dog which runs across an infected farm may carry easily in the dirt on his feet the virus of this most contagious of animal diseases to other farms, and thus spread the disease to the neighboring herds. In infected localities it is absolutely essential, therefore, to keep all dogs chained and never to allow them off the farm except on leash.

There are, however, many other maladies in the spread of which the dog takes an active part. In Bulletin 260 of the United States Department

of Agriculture, "The Dog as a Carrier of Parasites and Disease," it is pointed out that rabies, hydatid, ringworm, favus, double-pored tapeworm, roundworm, and tongueworm are often conveyed to human beings in this way. It occasionally happens also that the dog helps fleas and ticks in transmitting bubonic plague or the deadly spotted fever.

Hydatid disease is caused by the presence in the liver, kidneys, brain, lungs, and other organs, of a bladder worm or larval tapeworm. Bladder worms are often as large as an orange and may be larger. A dog which is allowed to feed on carrion or the raw viscera of slaughtered animals, may eat all or part of a bladder worm, containing numerous tapeworm heads. These tapeworm heads develop into small segmented tapeworms in the intestine of the dog. The tapeworms in turn develop eggs, which are passed out in the excrement of the dog. They are spread broadcast on grass and in drinking water, where animals can very well eat them, and thus become infected. The hog is particularly liable to this disease because of its rooting habits. The eggs may get into human food, and persons who allow dogs to lick their hands and face also run the risk of getting the eggs of the tapeworm in their systems.

Prevention on the farm consists in so restraining the dog that he cannot get at carrion or raw viscera. Viscera should be boiled before being fed to dogs, and should never be thrown on the fields. If not cooked and fed, viscera and carcasses should be burned, buried with lime, or so disposed of as not to be accessible to dogs. Proper feeding of the dog is essential, and the owner who does not feed a dog properly has no right to keep one.

The parasite which causes gid in sheep somewhat resembles the hydatid worm. A dog allowed to eat the brain of a giddy sheep may swallow this parasite and later distribute the eggs of the resulting tapeworm over the pasture. Sheep, while grazing, swallow the eggs with the grass which they eat. In the case of sheep dogs it is important to administer vermifuges often enough to keep them free of these worms. In the case of sheep measles, the bladder worm in the meat, typical of this disease, is swallowed by the dog, and again the tapeworm eggs are passed by the dog to grass or water, and there are eaten by sheep.

Of the external parasites which dogs may carry to animals, fleas and the various kinds of ticks are both troublesome and dangerous. The remedy is clear. The owner must keep his dog clean, not merely for the comfort and happiness of the dog, but to prevent it from becoming a carrier of disagreeable and dangerous vermin.

These reasonable measures, important to the stock on the farm, have a direct connection with the health of the family. Where ringworm or other skin diseases break out among the children, or the worm parasites develop, it is well to determine whether a dirty or uncared-for dog

may not be carrying infection on his skin or hair, or be conveying disease from carrion directly to the food and persons of his friends. Even if no one is infected with disease, the folly of allowing a dog to remain dirty and have the freedom of a home where personal cleanliness and hygiene are respected, is apparent.

CANCER IN THE UNITED STATES.

DR. BEITLER, Registrar of Vital Statistics, State of Maryland, has prepared some very interesting tables showing the mortality of cancer in the registration area of the United States during the decade 1904 to 1913.

The number of deaths, in the registration area, from this cause has increased from 23,295 in 1904 to 49,928. This corresponds to a rate of over 70 per 100,000 in 1904 and nearly 79 per 100,000 in 1914. Dr. Beitler's analysis shows the steady increase, not only in the number of deaths, but in the death rate in practically all the years of the decade, the increase in the rate amounting to 12.5%, comparing the first with the last year of the decade.

Facts already well known in regard to the prevalence of this disease are clearly brought out in this study: The greater frequency of cancer in the females than in the males; the greater increase in the rate among the males than among the females; no marked increases in the mortality up to the fortieth year of life, after which the death rate per one thousand shows a progressive increase; the greatest number of deaths between the ages of 60 and 70, closely followed by the age-group between 50 and 60.

The most frequent site of cancer shown in the table is cancer of the stomach and liver, from which 31 out of every 100,000 people died in the year 1913. The next in order of frequency is that of the female genital organs, the mortality for which was 12 per one hundred thousand. Cancer of the intestines showed a mortality of 10, cancer of the breast one of seven per one hundred thousand of the population.

The most marked increase is seen in cancer of the intestines. Next in order was the increase of 40% of cancer of the mouth. Then cancer of the breast with 20%, cancer of the stomach and liver with 19% increase.

The conclusions Dr. Beitler draws are that cancer mortality is increasing, that the increase is real, that the question of refined diagnostic methods and the inclusion of border-line cases cannot be a large factor in determining the rates; that it is hardly probable that a physician of a decade ago was so inefficient as not to be able to recognize advanced cancer; that the changes in the composition of the population, that is, in the sex and age distribution, were so slight that the effect on the increase in the specific rates was negligible.

The paper is interesting just at this particular time when the discussion of the increase in the mortality from cancer has taken on a new impetus by reason of the campaign directed by certain scientific organizations.

As pointed out in the *Bulletin* of Nov. 13, the Boston Department of Health proposes in 1916 to make its cancer statistics highly accurate by securing, wherever possible, additional information from the physician in all deaths reported from cancer.

A disease which is responsible for more than five per cent. of all deaths, which appears to be definitely on the increase, and which brings misery and suffering wherever it occurs, demands our serious attention. The Department of Health counts on the physicians of this city to coöperate with it in securing light on the nature and mode of spread of this obscure malady.

Correspondence.

THE PUMP ROOM AT BATH IN SMOLLETT'S TIME.

Boston, Dec. 4, 1915.

Mr. Editor: Dr. Sunderland's recent book on Old London's Spas, Baths and Wells* reminds us of the graphic description of Bath and especially of the Pump Room, written by Matthew Bramble to Dr. Lewis in the tale of Humphry Clinker. Sir Walter Scott says, (preface to Smollett's works), "The portrait of Matthew Bramble, in which Smollett described his own peculiarities, using towards himself the same rigid anatomy which he exercised upon others, is unequalled in the line of fictitious composition." The letter relates some of the trials and tribulations of getting accommodations at Bath of a suitable nature, and then describes experiences at the bath as follows: "Two days ago I went into the king's bath, by the advice of our friend C—, in order to clear the strainer of the skin, for the benefit of a free perspiration, and the first object that saluted my eyes was a child, full of scrofulous ulcers, carried in the arms of one of the guides, under the very noses of the bathers. I was so shocked at the sight I retired immediately, with indignation and disgust. Suppose the matter of those ulcers, floating in the water, comes in contact with my skin. I would ask you what must be the consequence? Good heavens! the very thought makes my blood run cold! We know not what sores may be running into the water while we are bathing, and what sort of matter we may thus imbibe, the king's evil, the scurvy, the cancer and the pox, and, no doubt, the heat will render the virus the more volatile and penetrating. . . .

"But I am now as much afraid of drinking as of bathing, for after a long conversation with the doctor about the construction of the pump and the cistern, it is very far from being clear with me that the patients in the pump room don't swallow the scourgings of the bathers. I can't help suspecting that there is, or may be, some regurgitation from the bath into the cistern of the pump. In that case what a delicate beverage is every day quaffed by the drinkers. . . .

"The very air we breathe is loaded with contagion. We cannot even sleep without the risk of infection. I say infection—this place is the rendezvous of the diseased—you won't deny that many diseases are infectious, even the consumption itself is highly infectious. When a person dies of it in Italy, the bed and bedding are destroyed, the other furniture is exposed to the weather, and the apartment whitewashed, before it is occupied by any other living soul."

As Smollett was born in 1721 and died in 1771, and he was undoubtedly quoting from his own experience, his statements bespeak keen knowledge, and a surprisingly advanced position as regards sanitation for the times in Italy. This last statement was undoubtedly the result of Smollett's actual experience and observation in Italy, as he was a resident of that country for some years.

Very truly yours,

WM. PEARCE COUES, M.D.

31 Massachusetts Avenue.

A CORRECTION.

Boston, Nov. 17, 1915.

Mr. Editor: I wish to protest against the headline set over the very inaccurate account in the daily press of my recent talk at Evans Memorial. The mistakes in the body of the account are not, most of them, very vital, but to represent me as saying that "nine-tenths of doctors guess" is in the first place false, as I never said it, and in the second place meaningless. If it means that nine-tenths of doctors sometimes guess, it must be true of ten-tenths. If it means that nine-tenths of them habitually guess or guess nine-tenths of the time, as many would suppose on reading the headline, it is in my belief entirely untrue, and very unjust to the body of the medical profession.

I am not trying to contrast hospital physicians with other physicians, but to contrast the treatment which any physician can give, when he has the advantages of hospital laboratories and instruments of precision, with the treatment which that same physician or any other could give without those aids. It is a difference not of personalities but of methods, and I protest against reports which make it appear falsely that I think ill of the efforts and fidelity of most physicians.

RICHARD C. CABOT, M.D.

SOCIETY NOTICES.

THE NORFOLK DISTRICT MEDICAL SOCIETY.—A regular meeting of the Society will be held in the Amphitheatre, Building A, Harvard Medical School, December 28, at 4 p.m. sharp.

A symposium on Cancer by members of the Huntington Memorial (Cancer) Hospital staff will occupy the first hour, after which a clinic will be held at the Hospital.

Supper will be served in the Library of the Medical School, Building A, at 6.30 p.m.

BRADFORD KENT, M.D., Secretary.

MASSACHUSETTS GENERAL HOSPITAL CLINICAL SOCIETY MEETING on Monday, December 27, 1915, in the Out-Patient Amphitheatre, 7.15 p.m.

1. "Pneumonia in Children, with especial reference to the x-ray as a diagnostic feature," Dr. Darkin.

2. "Medical Experiences in Arabia," Dr. Paul Harrison.

3. Presentation of pathological specimens of exceptional interest.

ELLIOTT C. CUTLER, M.D., Secretary.

FOOT STRAIN AND OTHER COMMON FOOT DEFECTS.

By HERMAN W. MARSHALL, M.D., BOSTON.

[From the Orthopedic Clinic of the Massachusetts General Hospital.]

NUMEROUS disappointments in treatments of common foot troubles occur notwithstanding our extensive knowledge of these conditions; and patients and physicians both are surprised very frequently at unexpected poor results of medical care; yet it seems nearly impossible to discover really new facts relating to feet. The writer believes accordingly that further advances must be made mainly through more careful examinations of what is known now but commonly forgotten.

Foot strain and other defects will be illustrated in this paper by a number of actual cases; and these will be followed by a discussion of the facts presented, concluding with a few revised elaborated general principles of treatment. Numerous photographs are used to facilitate descriptions, several different pictures of the same case being employed when they give added clearness. Soles of feet have been photographed with patients standing on a thick glass plate with a mirror arranged beneath it so as to reflect images conveniently into the camera, thus securing

weight-bearing positions. Only those facts in each history are reported, for the sake of brevity, that relate particularly to the features being illustrated.

A rough grouping of cases has been made into:

- (1) Simple relaxations and strains.
- (2) Rigid flat foot and allied conditions.
- (3) Foot strain accompanying other distinct pathologic states.
- (4) Miscellaneous lesions confused or associated with foot strain.

SIMPLE RELAXATIONS AND STRAINS.

Lack of order and completeness in treatment. The first case, Figs. 1, 2, 3, 4, is that of an eighteen year old girl who slowly developed weakness and pain in the feet six weeks before an orthopedic surgeon was consulted. He immediately recognized that the shoes were too tight and that the toes were cramped, also that the feet were relaxed and slightly pronated. Adhesive plaster supports were put on the ankles and larger, better shaped shoes with lower heels were recommended. Figs. 1 and 2 show the slightly pronated relaxed foot with slightly crumpled toes. Fig. 3 shows the original shoe worn, and Fig. 4 the recommended one. The patient returned in two weeks with symptoms increased, having been obliged to give up wearing the prescribed shoes on account of the greater discomfort which they produced. She gave a history on further questioning of recent loss of appetite and weight, and she looked pale and sallow.

New directions next were given to return to the original shoes until local pains subsided, then to change again gradually to the ones recommended. The feet were restrapped meanwhile, strappings being changed frequently enough to give continuous support. Tonic-eliminative drugs were prescribed

at the same time and in three weeks she had improved greatly. Her appetite was much better, the pallor of the face had disappeared, she was feeling in better spirits, and foot symptoms had practically gone. In another week she had made the change to the better shoes and was able to dispense entirely with artificial supports.

First observations made in this case were correct ones, but the trouble arose from omissions

1

2

in considering facts later brought to notice; and the enormous numbers of persons who adjust their footwear without proper medical advice obviously owe poor results obtained from arch supports and orthopedic shoes to similar omissions. Treatments must be something more than merely local mechanical ones. General conditions have to be thought of in every in-

stance because a large proportion of all cases of simple strain give histories of overwork, debility, "auto-intoxication" or other vague run-down states which should have medical care to ensure quickest recovery.

Physicians themselves too frequently treat foot strains as mechanical weaknesses, to be supported simply with mechanical props, or they tinker surgically with feet to improve only local structural peculiarities. Such mechanical or surgical methods are necessary for success very often, yet the fact remains that failures which still occur after them originate in neglect of internal medical treatments. The latter correct complex physiologic peculiarities which all patients possess in addition to their anatomic ones.

Too extreme abrupt changes. Tolerance of high heels. The second case, Figs. 5, 6, 7, 8, is a well developed, muscular young woman of twenty-two years. She is a diving girl in a theatrical troupe. Her friends told her that shoes with high heels and pointed toes were bad for the feet, so she purchased some flexible, broad toed, low heeled ones, making an abrupt, extreme change from one to the other. Furthermore, she had been wearing store arch supports in the first ones.

The result of the change was that muscles of feet and legs became very tired with additional continuous work they were suddenly compelled to do, and finally one fatigued ankle was so badly twisted that some of the small ligaments of the foot were injured, ecchymoses appearing beneath the skin. Complete rest in a plaster cast was necessary for a few days; and then, as the patient still desired to try to become accustomed to the better shaped shoes, the feet were firmly strapped and she

5

6

7

8

9

10

was allowed to walk. She persevered for a month, but finally, owing to the difficulties in obtaining medical attention regularly, she went back to the old shoes with supports. Simple medicines tried in routine manner during the period of treatment produced very little change in her symptoms, as was anticipated, for evidently bad results could be traced easily to the change made from nearly a maximum to nearly a minimum amount of support. Original shoes are figured in 5 and 6, and improved snapes in 7 and 8. This case represents the unskillful use of a very useful kind of footwear, and also exhibits the tolerance which is shown for high heels when feet have become accustomed to them.

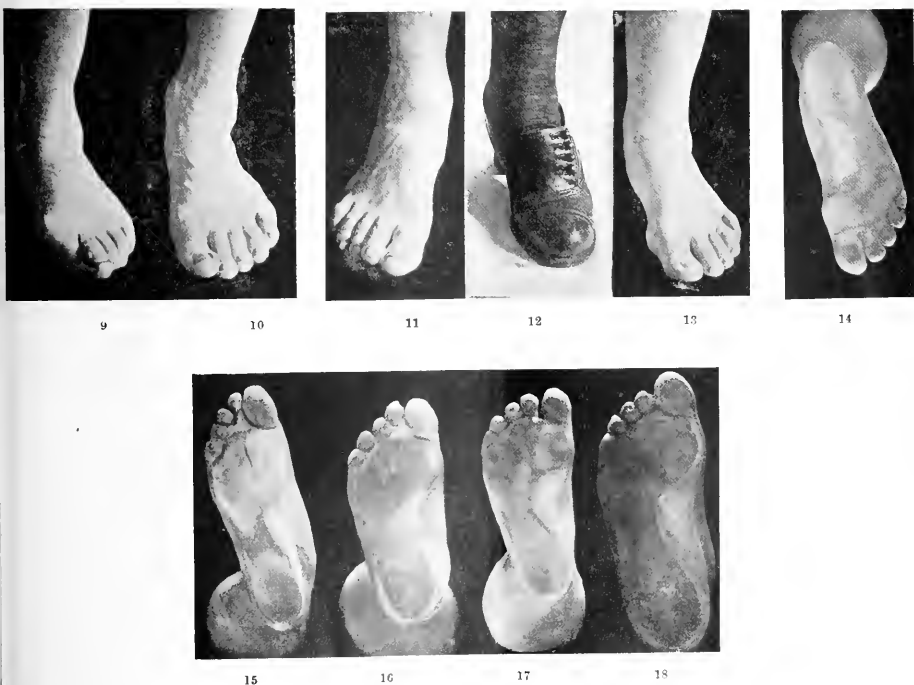

Deformities without Symptoms. *Symptoms without Deformities.* Figs. 9 and 10 are introduced to show that marked anatomical peculiarities are not necessarily associated with painful pathological symptoms. The fact that pathological symptoms may be present in the absence of great anatomic variations is indicated in Figs. 11, 12, 13, 14.

The foot figured in 9 was declared by the patient to be normal and to have been so for many years. This statement means that structural peculiarities developed so gradually that functional changes compensated perfectly for anatomic ones without destroying at any time the usually healthy

balance. It shows that symptomless hallux valgus is possible since this man is at work regularly, using the feet an ordinary amount. The flattened, pronated foot in Fig. 10 is symptomless, while the other foot of the same person, Fig. 11, although better looking, is weak and painful from an old injury.

The foot and footwear figured in 12, 13, 14 appear fairly good, yet acute symptoms of several weeks' duration were complained of. The foot is somewhat pronated, but not more so than many average symptomless feet, the toes are not crumpled, the longitudinal arches have not sagged much and the shoes are of good shape and size. There are many feet of worse appearance in which no symptoms are noticed, and it seems this case fairly presents pathologic symptoms without marked anatomic peculiarities.

Variations in Shapes and Sizes. "Normal looking" is a term frequently used loosely in descriptions of feet, but it possesses limited significance when long narrow types, Fig. 15, short broad ones, Fig. 16, unusually developed feet, Fig. 17, and variations in sizes, Figs. 17, 18, are noted. The photographs were taken at the same distance from the camera under similar conditions and are directly comparable. All these might be called fairly normal looking, and they demonstrate that there are wide individual variations in shapes and sizes which

should be recognized as individual peculiarities with very little pathologic significance.

Foot plates in simple relaxations and strains.

(A) A man desired some new plates to replace old ones which he had worn and broken. Figs. 19, 20, 21, 22, 23. He was six feet, four inches tall, weighed over two hundred and fifty pounds, was middle aged and worked in an iron foundry. His feet were large, relaxed, and flattened as shown in 22 and 23. Impressions of the feet were taken and a pair of low, flat plates were made. Fig. 21. These unexpectedly proved very uncomfortable, because they forced up transverse arches too much and did not afford enough support at inner edges of the feet. They had to be discarded in spite of much tinkering and after considerable perseverance from the patient. A second pair was made which proved entirely satisfactory. Figs. 19, 20.

The difficulty in this case was the failure to inquire sufficiently at first about plates which had been broken, as later it was found they had supported him just as did the last pair made.

The subsequent history of this patient was as follows: He was cautioned against unnecessary use of foot supports and advised to get accustomed to the lesser support afforded by the discarded flat plates. This he succeeded in doing in two months,

and then at this rather late date it was observed he was pale and anaemic looking although of unusual muscular strength and of large stature. Medicinal tonics were prescribed and these seemed to hasten his recovery appreciably, for in another month he was feeling much improved in health and had discarded all supports.

(B) A middle aged woman of average height and of slightly more than average weight first tried foot plates, then very flexible shoes, and finally shoes with moderately stiff shanks, yet still continued to have foot symptoms. Figs. 24, 25, 26. Like many other persons, she came for advice, desiring something new in way of treatment, but she was relieved soon by usual methods. First, she had consulted a well known orthopedic surgeon a year previously who fitted plates shown in Fig. 24. These relieved her and she passed quickly from his care. She continued to wear the supports for several months until they began to feel uncomfortable, instead of discontinuing them as soon as possible when the strain had subsided. She bought shoes with very flexible shanks next, and found the additional exercise they gave the feet after long continued support was beneficial for a few months. Finally, the feet grew less comfortable in flexible shoes, and stiffer ones were procured, Fig. 26, which served well for a few more months; but at last she came for advice again with a history of

19

20

21

22

23

24

25

26

27

28

29

mild chronic gastro-enteric trouble, recent overwork and with a sub-acute exacerbation of the digestive disturbance. Internal medical measures were then prescribed that had been successfully used previously in relieving similar gastric distress, and the feet were strapped. She was told to return to original foot plates until foot symptoms subsided, but to stop wearing them soon and to continue with moderately stiff shoes. She was also told to expect a return of foot symptoms whenever she became tired out for protracted periods, run down and her digestion upset. It was explained to her that vascular peculiarities probably undermined healthy conditions of the feet at such times and weakened them whether plates were worn or not, also regardless of special kinds of footwear. She responded promptly to strappings, plates and medicines, and within a few weeks needed no further care.

(C) A slender, rapidly growing girl of thirteen wore plates for twelve months continuously and had a recurrence of foot strain at the end of her school year. Figs. 27, 28, 29. She wanted to know what to do when her arch supports were no longer satisfactory. Examination showed the slender feet slightly relaxed, Fig. 28, and the shoes large enough and of fairly good shape, Fig. 29. The steel plates were made of very light spring steel, Fig. 27, and were doing their work just well enough. The treatment suggested was rest accompanied with a few simple hygienic regulations, and the feet were temporarily supported with straps. She was told to change neither plates nor shoes, and that presumably she would need artificial supports for some time while she continued to grow rapidly. In three weeks her symptoms had subsided and she did not discard the plates which she had erroneously judged to be worthless.

(D) A middle aged woman had very badly relaxed feet. She had drooping shoulders, poor posture and was generally relaxed although of average stature and weight. She had been in this debilitated state for many years. Fig. 30 shows her foot without weight, and Fig. 31, with weight upon it. The feet were strapped and tonics prescribed but their good effects were transitory. These treat-

strain of the plantar fascia resulting in pains in the heels. The patient was told by a number of orthopedic surgeons that she must endure some discomfort but she finally consulted another orthopedist who fitted Whitman plates successfully which the writer figures in 32. These have given complete satisfaction for many months, but it must be added that the patient's general condition also has somewhat improved so that some credit must be given improved vascular states for good results seen.

33

34

35

(E) A middle aged woman who has been obliged to work very hard under poor hygienic conditions has chronically relaxed feet. Figs. 33, 34, 35. She has been through an experience similar to the preceding patient, has had made for her low, flat plates, also Whitman plates, and has tried special shoes, felt pads and straps. The most important prescription, proper regulation of personal hygiene, was impossible for a long time and consequently she has hobbled around at her work with the feet firmly bound up in adhesive plaster, because this method of treatment has afforded most comfort for many months. Finally the needed rest was secured and new Whitman plates recently fitted are proving satisfactory.

Flexible Shoes have been considered among the cases given and do not require further illustration. They may be beneficial or harmful, depending on the skill and understanding shown in their prescription. They are physiologic opposites of plates, and the same comprehensive handling is needed with them as with the latter.

RIGID FLAT FOOT AND ALLIED CONDITIONS.

It is impossible to discuss rigid flat foot very satisfactorily when so little is known of underlying vascular peculiarities which produce these conditions. We have no means of measuring clinically the quantitative variations occurring from time to time among all numerous constituents of blood plasma, although physiologists have demonstrated in blood of animals temporary variations among circulating food substances immediately after meals; and although it is possible now with rather complicated clinical tests to ascertain proportions of a few substances like circulating urates in given samples

30 and 31

32

ments did not compensate long for very bad personal care the patient took of herself. Pains in the heels were complained of, and felt pads were adjusted with a little temporary relief. Low, flat plates, similar to Fig. 24, were made and readjusted several times, but they caused pain in the calves of the legs when too low, and when raised produced

of human blood. The very large majority of quantitative proportions, however, have yet to be found among numerous waste products, food substances, intermediate chemical combinations and internal secretions present in this vascular soil, upon which all tissues depend directly for their health and growth.

All that can be said at present is that there may be some additional substance, or group of substances, or some unusual proportion of an ordinary constituent, in circulation in rigid flat foot which produces irritations of synovial membranes and increased stiffness in the muscles. There are no methods of telling surely whether muscle spasm in such instances is a simple reflex phenomenon, or is due directly to influences of circulating substances upon muscles, or whether there are combinations of these two theoretical possibilities. We do know, however, that circulating bacteria, lodging and developing within joints, will set up inflammatory changes and that the latter may produce joint adhesions. It is a well known fact also that there is often increased reflex spasm in muscles controlling inflamed joints. It seems not improbable, therefore, sometimes that a group of bacteria, or their toxins, may be causative agents in rigid foot conditions. Different grades of virulence in bacteria and in bacterial products are recognized, and make it easy to account theoretically for all the many varying degrees of stiffness which are found clinically in feet, as the latter are affected by these variable irritants. At times there appear to be selective actions in these unrecognized substances, or special lowered resistances in certain groups of muscles and ligaments, that result in some parts becoming more affected than others. This is the case in spasm of peroneal muscles, also in osteal changes at insertions of Achilles tendons and plantar fasciae, where calcifications and spur formations frequently occur, as will be shown later. Fig. 63. Discussion of selective actions of circulating substances and resistances of particular tissues, however, cannot be entered upon in this paper.

We know only that some feet gradually become painful and stiff instead of becoming painful and pathologically relaxed, also that rigid types often run longer courses than mild simple relaxations. Benefits are derived in rigid states from protective strappings and supports, as in

relaxed ones, but in addition there often are needed in rigid types ether manipulations to break adhesions and to restore normal positions. Plaster casts are required too for complete rest and to preserve corrected positions. Local spasms of peroneal muscles have been treated by divisions of peroneal tendons to prevent increasing deformity, but underlying causes are not influenced by this method.

Two cases only of rigid feet are figured because photographs resemble so closely the relaxed conditions already shown.

(A) The first is a school girl of fifteen years whose feet gradually stiffened and became painful. She is a strong, healthy appearing girl and no etiology factors for her troubles have been discovered. She recovered completely in six months' time with the aid of supportive strappings, and with foot plates and tonics. Figs. 36 and 37 indicate the appearance of the feet, showing that they exhibit very little pronation. Motions of the feet in all directions were considerably limited, and there was stiffness in both lower legs and in both feet, but no evidence of spastic paralysis of central origin.

(B) The second patient is a woman of sixty, with rigid flat foot of several years' duration. Peroneal muscles are affected more than others but all are involved. There is a moderate varicose condition of the veins and longitudinal arches have sagged. Figs. 38 and 39. Strappings and foot plates together make this patient so comfortable that she prefers them to an ether manipulation and plaster casts. She has been given tonic drugs and eliminants with slight benefit.

(C) An interesting condition is shown in Fig. 40. This young girl of sixteen had a very flexible relaxed foot until she twisted the ankle severely twice, thus setting up a chronic inflammation. Marked tenderness and some abnormal swelling are present now over the external malleolus. These pathological symptoms probably indicate strained or torn ligaments for x-rays show no bony defects. The muscles, although weakened and relaxed, respond quickly still to protect the ankle, as the tightly contracted extensor tendons indicate in the photograph. They tighten quickly and relax again immediately when shifting strains upon the ankle due to motions of the body cease.

The differences between muscular action in this last traumatic case and sluggish changes of tense muscles in the first mentioned rigid flat foot case are so obvious, that it requires very slight imagination to picture some circulating ir-

ritant in some cases acting upon joints, or muscles, or their controlling muscular nerves, to produce continuous increased muscular tenseness. The same tonic-eliminative medicines do not have as marked effects in treatment usually as they do in relaxed debilitated conditions, yet they have been prescribed with considerable benefit apparently in some instances. There seem to be no good reasons, moreover, why attempts should not be made to put circulating blood into best possible condition in these rigid types as well as in debilitated persons; and, when simple routine measures fail, why consultations also with medical internists should not be made freely to secure correction of difficultly regulated vascular tendencies.

FOOT STRAIN ACCOMPANYING OTHER DISTINCT PATHOLOGIC STATES.

Infantile paralysis often leaves patients with foot deformities which require leg braces and surgical operations. These special methods of treatments cannot be discussed, but foot plates are frequently used also to redistribute pressures and to assist in restoring foot balance. Plates are used besides to minimize static strains and to increase the comfort of patients with progressive deforming arthritis, and after fractures of leg and ankle bones.

(A) A case of infantile paralysis in a young woman of eighteen is seen in Figs. 41, 42, 43, 44, 45 46. She previously had her foot deformity partly corrected by operation, and since then with assistance of the plate figured in 43 and 44, can walk several miles and dance as much as desired. The appearance of the supported foot in a low shoe is shown in Fig. 46.

(B) A case of arthritis deformans in a woman of fifty is shown in Figs. 47 and 50. This patient is able to walk as much as needed for management of a home and the care of an invalid woman of eighty who depends wholly upon her. She finds that plates with flanges, figured in 48 and 49, help to make her walking much easier.

(C) A case of fracture of both leg bones above the ankle, followed by an open operation with bone grafts is shown in Fig. 51. The swelling had not entirely subsided when the photograph was taken and the ankle was then being supported with adhesive plaster straps. A plate was fitted to this foot to relieve new strains developing from unavoidable slight changes occurring in anatomic relations after the injury. This plate will be worn until new compensatory changes in bones, ligaments and muscles can take place slowly and until a new normal balance is thus established.

(D) Figs. 52 and 53 show the pronated feet of a middle-aged patient with cardio-renal trouble. The ankles of this individual frequently become edematous and circulatory disturbances aggravate tendencies toward pronation of the feet. Low flat plates were fitted successfully almost immediately when advice was sought, because of the chronicity of the cardio-renal trouble with the probability in consequence of continued foot weakness.

(E) Hallux valgus deformities are represented in Figs. 55, 56, 57 and 58. This topic is more or less concerned with foot plates, and it also is a common defect that cannot be dismissed without brief mention of advantages and limitations of operative measures. A young man of thirty wears shoes of good shape and size, yet shows symptomless hallux valgus in his left foot. Fig. 55. The right foot is seen in Fig. 54 with very little deformity. There have been no symptoms complained of and also there is no bursitis over the great toe. He can work regularly without any difficulty and is ordinarily

41

42

43 and 44

45

46

47

48 and 49

50

active on his feet in spite of the anatomic defect. He was told there was no urgency in his case if he didn't desire to have surgical treatment now; and that he could safely wait until the foot troubled him.

A middle-aged woman had feet with painful bunions, the latter being of several years' continuous duration and they had resisted protracted treatment with the usual bunion pads. The feet are shown in Figs. 57 and 58. She was advised that she should have an operation immediately to straighten the toes and have the bursae surgically treated at the same time; but that afterwards she might need plates to hold the anterior arches of the feet properly if heads of first metatarsal bones were removed. Long duration of symptoms was the deciding factor in this instance.

Fig. 56 shows a hallux valgus condition in a patient suffering with arthritis deformans (atrophic

arthritis, rheumatoid arthritis). This foot, and left one of the same individual, Fig. 47, were operated on eight years ago and both great toes were straightened. Further slow contractures of muscles resulted, however, in considerable recurrence of the original deformity, yet this patient is convinced that the operation was a distinct benefit because there has been less pain in the feet since; and she can walk fairly well now with plates in spite of the deformity.

(F) Finally, relations between poor postures and foot strains deserve notice. Persons with drooping shoulders, relaxed back muscles and prominent abdomens frequently complain of foot pains as well as back aches. Such relaxed postures tend to make individuals stand with thighs rotated outwardly slightly more than usual, and with toes in consequence pointing outward to undesirable degrees.

51

52

53

54

55

56

57

58

toeing outward shifts the pressure of body weight upon the feet inward toward their inner edges and increases the strain upon longitudinal arches, with the result that painful symptoms at times develop.

Another good explanation for associations of foot strains with faulty postures lies in the reasonable assumption that circulating blood of poor quality affects muscles and ligaments of feet the same as it does back muscles and ligaments, and that parts which happen to be the weakest succumb first. Clinical observations harmonize with this view, and there are instances in which foot symptoms are followed by back involvements, or vice versa, back aches followed by foot pains, according as muscles in the one locality are more or less resistant than muscles of the other part; also of back aches or foot strains occurring independently of each other when backs and feet show still greater relative differences in their healthy vitalities. Both explanations should be accepted, and in the case figured in 59, 60, 61, 62

local supports, exercises, and medicinal tonics were prescribed.

The patient is a middle-aged woman who has complained of back weakness for many years, and recently this abruptly increased, while simultaneously foot strain was noticed. The spinal-abdominal support figured in 59 felt very comfortable when it was fitted and relieved back weakness immediately. The feet were made comfortable with temporary strappings, and tonic-eliminative drugs were administered. Within a few weeks foot-strain passed away and the back felt the best it had for years. It will be noticed in the photographs that the back support probably does not change the positions of abdominal organs very much, and it happens also there has been relief of foot symptoms without great change in the habitual position of the feet, so that the second explanation given above appears in this case perhaps more important than the first mentioned one. The outwardly turned foot of the

patient is shown in Fig. 62. Fig. 61 shows the patient's appearance with usual corsets previously worn readjusted over with brace pictured in Fig. 59. In all simple relaxations and strains of the feet, examinations of postures therefore should be made and treatments prescribed for backs when necessary on account of etiological relationships existing between them and foot defects.

MISCELLANEOUS LESIONS CONFUSED OR ASSOCIATED WITH FOOT STRAIN.

(A) Spurs of the os calcis sometimes are accompanied with painful symptoms, as is well known, and may be confused or associated with static foot strains. Fig. 64 shows a spur of considerable size without symptoms in a healthy man of forty-one years. This patient had his foot injured in an automobile accident, and the x-ray incidentally revealed the peculiarity in the heel, but there was no tenderness upon pressure over the projection. Fig. 63 shows a heel with less bony change at insertions of plantar fascia and of the tendo Achillis. These have been accompanied by painful heel symptoms of mild degree for two years continuously. The patient is a rather heavy woman of fifty years and she has worn arch supports without benefit. Operation was advised immediately in the latter instance and delayed in the first one until pathological symptoms make their appearance.

(B) Figs. 65, 66, 67 deal with hypertrophic bone changes in the first metatarso-phalangeal joint of a middle-aged woman. She had worn tight shoes for many years, and without apparent cause the left foot gradually became sore in a small spot between the first and second toes. The condition was first thought to be a simple anterior arch strain, but x-rays revealed bony changes shown in the illustration. See semi-circular space of Fig. 67. Palpation also showed a small tender indurated lump concealed between the toes in a location corresponding to the bony lesion. Small felt pads placed below and between the toes protected the tender region, and broader shoes were recommended. The front of the foot was snugly strapped meanwhile until it became slowly accustomed to the increased space, for the patient was quite helpless and unable to walk barefoot, on account of increased pain when the foot was not supported. Fig. 65 shows the x-ray of the corresponding joint of the normal right foot, and Fig. 67 is a photograph of the affected left one. The nature of this pathological process is very obscure, but undoubtedly continual wear of tight shoes furnish an important mechanical element, and there may be some infectious factor, as the tender indurated lump in the soft tissues suggests.

(C) Locations of infectious processes vary, as is illustrated by the feet figured in 68 and 69. The right one is symptomless, but the second metatarso-phalangeal joint of left one has been nearly rigid

59

60

61

62

63

64

for several years, and the patient has recently had pains in the front part of this foot and calf of the leg. Plausible etiologic factors in this case are many carious teeth, since painful symptoms have subsided after dental care combined with local mechanical supports, and the stiff toe has become somewhat more movable.

(D) Skin lesions have to be mentioned as being confused by patients with pains of foot strains. Burning sensations associated with chronic inflammatory processes in the skin frequently are thought to be flat foot and also the painful pressure of calluses is sometimes attributed to foot strain. Fig. 70 shows an extensive callus of the front part of the foot protected by an adjustable leather cuff with attached felt pads to take the pressure off tender areas at heads of metatarsal bones.

DISCUSSION AND CONCLUSIONS.

Data enough have been given to indicate numerous details which must be memorized by the thorough practitioner, since any of them are liable to enter into the next case presented.

Errors commonly observed are those of patients or physicians who conclude, for example, that flexible shoes are harmful because some persons are made worse after their use while other patients are benefited by use of foot supports; or oppositely, that plates are bad because they do not relieve some individuals who are helped by exercises. Mistakes in these instances consist in comparing things which are unlike each other, and instead successes of one method logically should be compared with successes of the other, also failures with other failures. In addition, it is unjustifiable to compare supports with exercises because they are physiological opposites. They complement, not duplicate, each other's action in treatment. They are not antagonistic to each other, as some imagine, because different; and both are needed very frequently before normal functions are completely restored.

Another common error is to place so much emphasis on certain features, broad toed shoes and low heels, for illustration, that other facts are obscured which should enter into consideration. There can be no doubt that broad toes and low heels are ideal styles for persons who have never worn shoes; but in fairness it must be ad-

mitted that the majority of women still wear moderately high heels and shoes without extreme toes. They do this with less discomfort perhaps than the smaller group of women who are obliged from foot strain to wear more correct styles. Considerable maltreatment is compatible with continuance of normal foot functions in the large majority of persons, because compensating functional changes occur which offset slightly unfavorable conditions imposed by faulty foot wear. Eventually such defective conditions slowly become more comfortable and normal than original ones, when bones, muscles, and ligaments have accommodated themselves long enough. Efficiencies of the feet are lowered somewhat by these changes, yet they are good enough still for all practical uses; so that we should hesitate about making too radical changes in long accustomed styles of foot-wear of persons of middle age and past, when their foot symptoms are not very severe nor of long duration.

Misconceptions of the relative importance of anatomic and physiologic foot peculiarities perhaps are commonest and most important errors encountered. Anatomic peculiarities can be recognised at a glance, or if hidden, they are convincingly revealed in x-rays. Physiologic peculiarities on the other hand cannot be estimated readily, namely, the healthy vitalities of synovial and subcutaneous tissues, cartilage, bone and fasciae, as these various tissues resist mechanical frictions, strains, heat, cold and traumatic influences to which they are subjected. Physiologic peculiarities, strengths of muscles, tissue resistances, etc., are all dependent closely upon variable conditions of blood and lymph, but variations in vascular proportions from time to time unfortunately are almost entirely unknown.

In practice, naturally, therefore, intangible unknown physiologic peculiarities are easily forgotten or disregarded, and attention instead soon is directed entirely to easily understood structural variations. This error is of fundamental importance, having direct bearing on surgical procedures, internal medical treatments and orthopedic appliances. It creates strong tendencies toward unnecessary fitting of mechanical braces, toward too much surgery, and toward

over-estimation of the importance of anatomical features with corresponding underestimations of functional aspects of each problem.

Correct conceptions recognize complementary natures of anatomic and physiologic factors, that they are combined always with each other to produce the balance of health, and that they give rise to widely variable degrees of good health and ill health. Average good health always is a matter of balance between the two, and is possible with marked structural variations in the feet amounting even to deformities, provided there are also compensatory strengthenings and functional changes in foot muscles and ligaments. Figs. 63 and 64 prove conclusively that anatomic variations independently furnish no reliable indications of pathologic symptoms. In Fig. 64 the greater structural peculiarity is unassociated with symptoms, while the slight one in 63 has been accompanied by continuous tenderness and pain for many months. This does not contradict the statement, however, that the greater the anatomic defects are, the more severe will be the pathological symptoms produced, other things being equal. The truth simply remains that these other things vary so much in such subtle unrecognized ways that anatomic defects alone become unreliable indicators of symptoms.

The problem of what shall be done with obscure functional factors, which cannot be measured, yet which are so important because ever-present, has to be solved by indirect means except in a few instances where direct measurements are possible, as with muscle strengths. Osgood* and others have shown that measurable changes in muscle strengths do occur, that in foot strain there are relative weaknesses in muscle groups acting as foot adductors; but these interesting observations are about the only important physiologic studies that have been made upon feet.

All physiologic peculiarities, including muscular ones, can be treated and roughly diagnosed at the same time, however, from results of treatment, when hygienic regulations and drugs are tried in therapeutic-diagnostic ways; for, despite the impossibility of determining functional peculiarities or vascular proportions directly, yet pharmacology and human physiology respectively indicate physiologic action of drugs, and relations between organs. It is very simple to administer a few selected reliable medicines of well-known action in routine manner, and to stimulate well recognized physiologic activities of different organs, thus eliminating from circulation accumulated waste products and other unknowns which cannot be clinically identified; and when the blood has been kept in good condition continuously for a few weeks the tissues begin to respond noticeably to their improved environment and pathologic symptoms begin to abate.

* See Bibliography.

Details of drug administration cannot be entered upon in this paper, but practically it has been found that simple tonic-eliminative measures accelerate relief of many foot defects, as they also do other orthopedic troubles; and foot strains should not be thought too trivial to be treated according to best medical principles, if there are to be any differences between medical care and haphazard purchases at stores of plates and shoes.

Abnormal symptoms are most reliable criteria by which to judge the lack of balance between physiologic and anatomic peculiarities. Feet should not be treated because they are flat simply, as some of our best athletes have symptomless flat foot; nor is it necessary to operate upon symptomless hallux valgus deformities or os calcis spurs because of anatomic considerations alone. Great severity or long duration of pathological symptoms occasionally present indications for immediate interference when structural defects are almost negligible, excessive use under average anatomical conditions being the principle causes in some of these instances.

Another error seen in practice in the furnishing of too much artificial support for weak feet, or giving right amounts of support for unnecessarily long times, thereby weakening muscles and ligaments from disuse.

Patients are fitted frequently with foot plates, but have no directions given them about discontinuing supports when symptoms have been relieved. Feelings of weakness noticed when plates are first removed, after having been worn for considerable periods, make such patients inclined to continue the use of plates to the detriment of the strength of their feet. This should be avoided by explanations made at the outset. An illustration has been given in the foregoing records with its natural outcome, *e.g.* the trial of flexible shoes.

Controversies have arisen over respective merits of low flat styles of plates shown in Fig. 24, and the balanced variety represented in Fig. 32, the latter being originally devised by Whitman. Both styles possess merit. Flat plates give enough support for relief in a large percentage of cases, as their successful, wide use demonstrates. They are more easily fitted than balanced types, but the latter prevent pronation and hold longitudinal arches more perfectly than low firmly set supports. Balanced types of plates can be made very comfortable, or purposely slightly uncomfortable so that they exercise foot muscles through variations in balance. Muscles will draw up inner borders of feet away from points of uncomfortable pressure of plates if the right degree of balance in the latter are secured. Balanced plates relieve successfully some very badly pronated flexible feet which cannot be held satisfactorily with other supports, but they are not entirely free from faults and may be improperly used to strain

muscles which are already overtaxed. At other times, when made with more comfortable balance, they occasionally afford really more support than is needed, and so tend to produce weakness or disuse more rapidly than less perfectly fitting flat plates.

When feet have been unnecessarily supported for long periods, plates gradually feel harder and harder as muscles functionate less and less. Flexible shoes which exercise the feet, or special foot exercises then will relieve these symptoms due to over-support. Exact degrees of artificial aid necessary from time to time will be seen to be variable quantities, depending largely upon muscle strength and muscle tone; and since muscles respond closely to variations in blood from time to time the extreme importance of keeping blood continuously at its best quality can be readily understood. In chronic debilitating diseases much artificial support is required, while in early healthy adult life none should be needed. The only fixed principle in practice with regard to supports is the one of determining and prescribing minimum amounts which are adequate for relief of symptoms in the particular stages presented. Abrupt extreme changes from very great to very little support are mistakes commonly observed, which it is hardly necessary to say should be avoided.

This paper has been prompted by the writer's experience in the Orthopedic Out-Patient Department of the Massachusetts General Hospital. To this clinic come great numbers of patients with foot troubles, who exhibit widest varieties of conditions, and among whom previous treatments have been variously good, bad, or indifferent. There are neglected cases and over-treated ones, self-directed cases, cases treated by so-called "foot-specialists," connected with shoe stores, and patients who have been in the care of medical practitioners. Efforts are being made continually by members of the clinic toward improving the efficiency of the department as much as possible under the imposed circumstances of limited time and many patients; and it was from study of the great variety of conditions exhibited in this wealth of clinical material that conclusions and general principles herein presented have been largely drawn, which are applicable in general practice.

GENERAL CONCLUSIONS AND PRINCIPLES OF TREATMENT.

1. Avoid routine use of any single special method.

2. As a starting point, observe the kind of shoes worn; pathological signs and symptoms in the feet; the amount of use of the feet demanded; the state of health and its recent changes; the past history and treatments; and then, proceed *gradually* to make necessary alterations and prescriptions in careful manner.

3. Remember that treatments have to be ended skillfully as well as begun properly, and ac-

cordingly discontinue the use of plates, straps, medicines, etc., at best times.

4. In simple relaxations and strains, or in rigid flat foot, support the feet with adhesive straps at the outset and simultaneously prescribe suitable tonic-eliminative drugs. Later, from responses to those two measures, and after taking into consideration all circumstances and social conditions of patients, continue with strappings, make changes in shoes, fit plates, prescribe special foot exercises, or suggest other manipulations, plaster casts, etc., as seems best according to physiological requirements of each successive situation.

5. Do not exaggerate the importance of easily recognized anatomic defects nor underestimate equal values of obscure physiologic peculiarities. Remember that all patients have vascular systems; that possibilities of blood variations have to be dealt with in all cases, and many times are only ways of attacking physiologic defects, furthermore, that regulations of vascular defects sometimes are simple although defects themselves are complicated or unknown.

6. Avoid unnecessary surgery, and too much treatment with orthopedic appliances, by taking into account first always the severity and duration of abnormal symptoms; and by remembering that pronounced anatomic peculiarities often are compatible with continued normal physiologic activities.

7. Treat special foot diseases in appropriate special ways.

8. Whenever there are recurrences in underlying causes of foot strains, or other defects, as quite commonly happens at irregular intervals, there are likely to be recurrences also of pathological foot symptoms. These must be expected in some instances, and decisions made then between repetitions of former successful methods and trials of novelties of uncertain merit. Much can be said in favor of adhering to well-tested efficient methods in preference to experimenting too quickly with doubtful new variations. Patients ought to understand the situation.

9. Explain to patients the limitations and possibilities of comprehensive methods and of single special ones sufficiently for them to understand the necessity of the former for best results, although they may be complicated and include a number of different stages. Demonstrate the inadequacy of any single method of treatment, old or new, in fulfilling the various requirements, likely to be met, and which shift from time to time in the same person. Make it clear that these common and comparatively trivial foot troubles require nearly as comprehensive understanding for their *skillful* treatment as serious orthopedic conditions in other parts.

THE PROGNOSIS OF INCIPIENT SENILE CATARACT.*

By DAVID W. WELLS, M.D., F.A.C.S., BOSTON,

Professor of Ophthalmology, Boston University Medical School; Ophthalmic Surgeon, Massachusetts Homeopathic Hospital.

To the lay mind the diagnosis of cataract is equivalent to a sentence of certain blindness at no very distant date. Unfortunately this opinion prevails with many medical men who have not given special attention to the eye. It is the purpose of this paper to show that a much more optimistic prognosis is justifiable. The importance of correcting this misconception can hardly be over-estimated. The definition of the word in the Standard Dictionary is "an opacity of the crystalline lens of the eye or its enclosing capsule resulting in complete or partial blindness." This is certainly a terrible doom to contemplate, and in many instances has induced great despondency and even melancholia. While the definition is true of the progressive type it is not true of a very large percentage of cases, the

FIG. 1. (Landolt.)

Schematic eye. a' Anterior or first principal focus; a , anterior surface of the cornea; H' and H'' principal points; k' and k'' nodal points; a'' posterior or second principal focus; $F.c.$, fovea centralis; $o'o''$, optic axis.

non-progressive type, for whom this is a most cruel misconception.

The eye is a most highly differentiated sense organ and the lens unlike any other tissue. It is double convex in form, 5 mm. in thickness and 9 mm. in diameter, situated just posterior to the iris, resting upon a concavity of the vitreous body. The posterior surface is slightly more curved than the anterior, but this latter has the property of increasing its convexity by the contraction of the ciliary muscle. This process is known as accommodation, and by it the eye is focused for objects at different distances. Embryology teaches us that it is entirely of epithelial origin. The anterior capsule is lined with a single layer of cubical cells which by a process of elongation grow into fibres which extend from the anterior to the posterior capsule.

In other epithelial structures the worn out cells are exfoliated; but here, as new cells are

formed, the older ones are squeezed together in the centre, gradually forming a nucleus, which increases as age advances, finally forming a hard centre. The enveloping substance is called the cortex. There is no definite line of separation

FIG. 2. (Landolt.)

The full lines indicate the crystalline lens, iris, and ciliary body in a state of rest; the dotted lines show the same in a state of accommodation.

between the two, but a gradual increase in density from without inward. In elderly people the refraction of the centre is often quite different from the periphery.

Meridional section through the crystalline lens.

FIG. 3. (Henderson.)

Showing growth of lens fibres from epithelial cells lining anterior capsule, the nuclei accumulated in the equatorial zone, and lines formed by union of ends of fibres.

The lens has no blood vessels, its nutrition being secured by absorption of lymph from the ciliary processes. The metabolism is, therefore, extremely slow.

A complete enumeration of the varieties of cataract would transcend the limits of this paper, but a few must be mentioned, with no further explanation than the names imply.

Congenital and acquired.

Primary and secondary.

Hard and soft.

* Read on Oct. 7, 1915, at the monthly meeting of the Boston section of the Massachusetts Homeopathic Medical Society.

The typical senile cataract is *hard*, is *acquired* and usually *primary*, but may be secondary in the sense that it may be influenced by some other diseased condition. It is either nuclear or cortical, depending on the location of the opacity.

The nuclear variety is simply an exaggeration of the normal crowding together of the worn out cells, a strictly senile change.

Common senile cataract is an opacity of the cortex of the lens, beginning at the periphery in the form of radial streaks. These streaks look grey with oblique illumination, and show as black lines with the ophthalmoscope. If they do not extend far into the pupillary area the sight is not at all affected. Later on they may have a stellate appearance following the lines of the uniting lens fibres.

This variety of cataract is seldom seen before the 50th year, and increases in frequency with older patients, yet it cannot be regarded as a physiological senile change. Regeneration of the new cells takes place more slowly and metab-

against cataract. . . The progress is sometimes rapid, sometimes slow, the latter especially in senile cataract, which not infrequently remains in an almost unchanged condition for years. Hence when we find in an elderly patient the

FIG. 4. (Haab.)

Ophthalmoscopic appearance with dilated pupil. *b* Zonular opacity with radial striae; *c*, Cortical opacity, immature, showing stellate figure.

olism, at all times slow, is less active. The normal sclerosing evidently predisposes to the formation of spaces between the fibres, which become filled with liquid which has a different refractive index from the fibres themselves, and thus form opacities. Fatty degeneration occurs in spots and lime salts are often deposited as the cataract matures.

If the patient be one who consults his oculist at reasonable periods, the latter will discover the trouble long before the patient is aware of it. These cases are often complicated with general faulty metabolism, and occasionally are of diabetic origin. Any disease which affects the nutrition, like glaucoma or uveitis, may be the primary cause and should receive the appropriate treatment.

Will it progress is a question no one can answer, so it is the consensus of opinion of most ophthalmologists that the patient should not be enlightened. Fuchs puts it thus, p. 415:

"No kind of medicinal treatment is effectual

FIG. 5. (Weichselbaum.)

Microscopic section of nearly mature cataract.

a, capsule; *b*, epithelium; *c*, cortical layer; *d*, anterior portion of nucleus; *f*, spheres of fatty degeneration; *g*, vacuoles; *h*, complete liquefaction of lens substance.

first stages of a cataract, which as yet produces no interference with vision worth mentioning, the indication is, in the interest of the patient, not to frighten him by communicating the condition to him, as he may enjoy good vision for several years to come."

Dr. deSchweinitz says of prognosis, p. 545:

"Incipient cataract in the form of striae in the anterior cortex need not doom the patient to rapid deterioration of sight, because the existing vision is often maintained for long periods of time. Spontaneous disappearance of senile cataract has been reported. . . Drugs do not exist which can dissolve a growing cataract."

The natural history of untreated senile cataract has, so far as the author knows, never been properly investigated. Various drugs have been advocated and each has had its vogue, but no one has yet been able to record any better success than follows the let-alone policy. In most cases the opacity is unchanged. Authentic cases of spontaneous absorption have been reported, and a certain percentage will progress to maturity. Most of the reports of success of a certain line of treatment have omitted to give the number of cases not benefited, so that nothing is proved. Cinneraria Maritima enjoyed a great reputation with the laity and some practitioners, but an investigation of the case made by the Homeopathic O. O. and L. Society some years ago showed that value was not proved.

The sub-conjunctival injection of potassium iodide was claimed to have the power of absorbing opacities. I tried this in a few cases, but

could discover no value. The x-ray flash was announced as a cure. I secured the apparatus, and with the coöperation of Dr. B. T. Loring, tried it on a dozen cases, but was doomed to disappointment. Cures have been reported with drugs administered homeopathically, but never under conditions essential to scientific demonstration. For a number of years I have pursued the policy of "*watchful waiting*," until it is evident that the opacity is increasing.

All cases of incipient cataracts have been indexed. From 1900 to 1915 of all private patients over fifty years of age, 23% had some demonstrable opacity in the lens, though in many cases the sight was but little if at all affected, yet by the accepted definition one must diagnose cataract. Sufficient time has now elapsed to report on those seen from 1900 to 1905. One-half had vision of .5 or better, that is, serviceable sight. Many have been watched at varying intervals for from 10 to 15 years. Of course many have been lost sight of, but as near as can be estimated not more than 1% of the truly incipient cases have matured and not more than 5% of the same have materially advanced. From this it appears that the prognosis of incipient senile cataract untreated is extremely good. Most of the cases which have come to operation have been nearly or quite mature when first seen.

Unless one can show that his results with a certain drug, internal or external, or the indicated remedy or the mechanical appliance are better than the untreated case, he has not proved the therapeutic value of his interference. Patients are so willing to be treated, especially if one uses the word cataract, that it takes some moral courage to desist. The coöperation of the family physician would greatly assist in the rational treatment of the case.

We refrain from using the word "cataract," but say truthfully "There is some slight opacity in the lens." A careful drawing is made to show size and location of the opacity for future reference. This is important, as vision may remain unchanged even with marked increase of defect. A laboratory urinalysis of a 24-hour sample is made and duplicate report sent to the family physician, who is apprized of the true condition. He is requested to go over the case carefully, and patient is advised that attention to general health will be most helpful. Any marked reduction in urea excretion is treated with high frequency auto-condensation three times a week for one month, when a second urinalysis is made to determine if excretion be increased. Refraction should be corrected frequently, as cataractous eyes are apt to undergo much change in this respect. Contrary to what some advise, the reasonable use of the eyes is encouraged, believing that if any accommodation be possible it will be beneficial—possibly improving metabolism. Eye grounds are studied

and any associated disease treated, especial attention being paid to lacrimal stenosis. This must be cured before any operation be undertaken lest the wound become infected from the contents of the sac. If a few probings fail to secure drainage the sac is extirpated.

The patient is requested to return in one month for observation and if no change be discovered, he is asked to return in three months. The case is then usually lost sight of until he needs a change in glasses. A certain proportion of cases will progress. Many ophthalmologists feel that these should be treated, though few of them agree upon the indications. For a number of years I have refrained from doing so, though I should not hesitate if the patient seemed unwilling to accept my let alone advice. Unfortunately many seemingly are satisfied, but are led astray by the great claims of cataract absorbers, and are apt to return to us for the extraction, impoverished by unprincipled fakirs. The progress of an untreated case is not a gradual loss of sight, as the process may become stationary at any period. Fortunately the two eyes are seldom equally affected, so that one retains good vision while the other is maturing. So long as the better eye is sufficient for reading, it is wise to wait for maturity, because with this maturity fluid forms beneath the capsule, loosening it from the cortex, thus allowing a much cleaner extraction. Efforts to hasten maturity have been used, such as massage of the capsule through corneal incision, but are now seldom resorted to. *There need, however, be no period of blindness.* With a preliminary iridectomy and a preliminary capsulotomy the immature lens may be safely extracted. Cocaine suffices and general anesthesia is resorted to only with an extremely nervous patient. The preliminary iridectomy is done three or four weeks before extraction. It necessitates a stay of three days in the hospital, but the patient is allowed to be up and about. Although it means two operations instead of one, it greatly facilitates the major operation by affording a field clear of hemorrhage from the iris. There is also less danger of iritic adhesions to the capsule. Incidentally it teaches the patient what is expected of him, allays his apprehension, and helps the surgeon to gain his confidence. The preliminary capsulotomy is performed if the lens is immature. It consists in introducing the knife needle through the cornea and incising the capsule. The object sought is the loosening of the capsule from the cortex by allowing the aqueous to penetrate it. It is done the evening prior to the extraction.

The quack advertisement "Avoid the terrors of the knife and take my absorption treatment" does seduce many otherwise intelligent patients to waste their substance. Help us to convince these people that the "terrors" are imaginary. The confinement in bed for three days with

both eyes bandaged is really the most uncomfortable part of the treatment. On the third day the eye is inspected and if the wound has healed, the unoperated eye is left unbandaged and the patient allowed to be up. A night nurse is always in attendance when both eyes are bandaged, but there is no restraint of the hands, as the operated eye is protected by an aluminum shield.

The statistics given by Knapp,¹ whose observations were based on a large number of cases at home and abroad, give the results as follows: "In all cases as they come, failures, 5%; moderate results, 10%; good results, 85%." It is, therefore, evident that a good prognosis is justified in the cases which advance so as to require operation. If one is losing his sight the most hopeful diagnosis is cataract. If the eye be normal in other respects, sight is usually restored.

The principal causes of failures are:

A diseased eye behind the cataract.

Infection, usually auto-infection, may occur, as it is impossible to secure perfect asepsis. Vision is usually lost, but fortunately this is extremely rare, perhaps 1 or 2%.

Post-operative hemorrhage from the retina is extremely rare but fatal to success.

Iritis, traumatic and from rheumatic diathesis, may leave a closed pupil but this can usually be remedied by a skillful Ziegler iridotomy.

Patients with incurable diabetes and nephritis are undesirable risks, but most surgeons feel it a duty to give them the chance. Naturally the statistics of a given operator will be greatly affected by the percentage of unfavorables.

CONCLUSION.

Most incipient senile cataracts never advance enough to need operation; therefore, we should avoid the term "cataract" and give the most hopeful prognosis until it is evident that it is progressive. Then, if it does mature, operation offers a good prognosis. If the sight of the better eye is insufficient for reading, the immature cataract of the more advanced eye can be safely removed, so there need be no years of partial blindness waiting for ripening. Certainly the patient is entitled to the most optimistic opinion which clinical history and experience warrant.

THE RADICAL TREATMENT OF PERITONSILLAR ABSCESS BY TONSILLECTOMY DURING THE ACUTE STAGE OF THE DISEASE.*

BY HARRY A. BARNES, M. D., BOSTON.

PERITONSILLAR abscess is a suppurative inflammation of the walls of the sinus tonsillaris. As the tonsil itself is in reality only a complicated mucous membrane containing a large amount of lymphoid tissue and covering the walls of the sinus, quinsy may be considered a submucous abscess of the sinus. The pus, therefore, usually is confined between the fibrous mucosa of the sinus (the tonsillar capsule) and the muscular walls of the fauces immediately subjacent to it,—the superior constrictor of the pharynx externally, and the palato-glossus and palatopharyngeus anteriorly and posteriorly respectively. The pus may be confined by inflammatory adhesions to a small area anywhere within this comparatively wide field; or it may dissect the capsule away from the muscles over a large portion of the sinus. As the sinus extends high into the palate, the latter type of abscess appears to be palatal in position, and may be opened and drained either through an incision in the palate, or one extending upward and outward through the superior wall of the supratonsillar fossa. Anterior and posterior abscesses, when their situation can readily be determined, are usually easily accessible by incision through the anterior pillar or between the posterior pillar and the tonsil. When, however, the pus is confined to the space between the body of the tonsil and the superior constrictor muscle, the task of reaching it by incision is not always an easy one. Every surgeon has probably had the experience of repeated failures to locate the pus in this class of case, which of all surgical affections is one of the most uncomfortable to the patient with which we have to deal. Some years ago Ballanger suggested a method by which such abscesses might readily and surely be drained with a minimum of suffering to the patient,—a capsular dissection of the tonsil backward until the abscess cavity is reached. Provided ankylosis of the jaw, nearly always present in quinsy, is not so great as to make access to the fauces difficult, this method is easily carried out and is practically sure of success. I had been using it for some time with satisfactory results, under a general ether anesthesia, when Dr. A. Coolidge, chief of the throat department of the Massachusetts General Hospital, suggested that the operation might be carried a step farther, and the tonsil then and there be dissected out completely. I confess that I was at first somewhat startled by the idea, having the old preconceived notions of the dangers of creating so large a wound in the presence of an acute streptococcus infection. On second

¹ Norris & Oliver System of Eye Diseases, p. 818.

* Candidate's thesis for admission to the American Laryngological Association.

thought, however, I concluded that our fears on this score were not only groundless, but were without a good theoretical basis. Subsequent experience has, I think, confirmed this.

The theoretical dangers of the operation are two: First, that a general anesthesia is not safe on account of the possibility of subsequent pulmonary infection from inspired pus; second, that it is always dangerous to operate on an acute inflammation of the tonsil, at least to do so extensive an operation as a tonsillectomy, because of the fresh field opened up for infection. On the first head I can say only that I do not believe that the danger exists, beyond that which may be present in the dissection of any tonsil, provided due care is taken when the abscess cavity is reached, to prevent with gauze sponges any escape of pus below the fauces. Very large peritonsillar abscesses are not suitable for this method of treatment, both because they may easily be drained by simple incision, and because their size makes a general anesthetic inadvisable. In these the large amount of pus might be difficult to manage in such a manner as to be sure that a considerable amount did not get below the fauces. In the smaller deep-seated abscesses a sponge on the end of a holder absorbs the pus perfectly as fast as it is evacuated. I have now operated on ten cases by this method, and in none have I had reason to believe at the time of operation that any pus was inhaled, nor has there been anything in the subsequent history of these cases that would suggest it.

Of the second danger, that of infecting a large fresh wound with the streptococcus, it may be said that both theory and observation show that this method is much safer than the usual treatment by simple incision. This incision through the palate or the anterior pillar *does* open a fresh field for infection, in that in some of its course at least it goes through more or less normal tissue, where inflammatory exudate has had no chance to place a protective barrier between the streptococcus and the general system. To this also may be added the possibility of opening one of the large veins of the sinus walls by a blind incision. A fatal case of general streptococcus infection, following such an incision, occurred at the Massachusetts General Hospital last year, which I have always felt might have been due to this cause. Moreover, a fresh cut immediately closes more or less completely, so that drainage is poor, not only from the abscess cavity itself, but from the newly infected area of the incision. When the tonsil is dissected out, however, the conditions are in every way more favorable. The sinus walls are everywhere protected from absorption of the streptococcus by marked inflammatory infiltration, and the only fresh wounds made by the dissection are those through the plicae anteriorly and posteriorly. It may be argued that the sinus walls everywhere are liable to injury; but if the dissection is carried out according to the description given later in this paper, there is but slight danger of this.

Add to these theoretical considerations the fact that after dissection we have, instead of a closed abscess sac and a poorly drained fresh incision, a simple open ulcer the walls of which are everywhere rendered practically impervious to absorption, and it will be appreciated that this radical treatment is far less dangerous from the standpoint of streptococcus infection than the older method of simple incision.

One other point makes this method of particular value,—the abscess may be treated with success much earlier than in any other way. Peritonsillar abscess has been said not to become suppurative until the fourth or fifth day of the disease. That this is not so, anyone may convince himself by dissecting out the tonsil on the third or even the second day. He will then find that the disease becomes suppurative early, and that the reason that pus is seldom found before the fourth day is that it is too deeply seated and too small in amount to be found with any degree of certainty by the method of incision. Tonsillectomy offers a practical way of safely cutting short these most distressing inflammations early in their course. It is advisable that it be done not earlier than the third day, however, as before that time the walls of the sinus are not sufficiently infiltrated to offer a suitable defence against streptococcus infection.

The operation of tonsillectomy in these cases differs only slightly from the usual procedure by the dissection method. It is essential that the dissection be a clean one, and that the muscular walls of the sinus be as little injured as possible. If one of the larger veins is opened, it seems to me that the chances of general streptococcus infection may be distinctly increased. To avoid this, it is necessary that the field of dissection should be seen at every step. Now these tonsils are always tightly adherent to the walls of the sinus, except over the area occupied by the abscess itself. It is difficult, therefore, to find the line of demarcation between the two after the first incision in the plicae has been made. The usual more or less blind evulsion of the superior lobe by blunt instruments or by probe pointed knives is dangerous, as the sinus walls are almost sure to be injured. To insure against this, I have found a pillar retractor essential. The one I have used is not unlike Killian's retractor for the lacrimal sac, except that the handle is longer, the blade broader and thinner and the curve somewhat greater. After the first incision in the plicae has been made, the retractor is inserted by an assistant under the free edge, and the plicae and pillar gently pulled outward and forward. At the same time the tenaculum holding the tonsil is pulled inward, so that the line of demarcation between the capsule and the sinus wall is easily discerned at the apex of the resultant V-shaped cleft between the two tissues. The lightest touch of a sharp knife serves to deepen and widen this cleft, which is in this manner extended backward until the abscess cavity is

reached. A gauze sponge on a holder is then inserted against the incision and the abscess cavity allowed gradually to empty itself. If there is a large amount of pus, several sponges may be required to absorb it. This, however, causes no embarrassment, as the stream may be cut off or turned on at will by the valve-like action of the plica and anterior pillar controlled by the retractor. When the pus has been completely evacuated, the dissection is again carried on as before until the tonsil is sufficiently freed to allow of the easy application of the snare.

The bleeding during this operation is surprisingly slight,—no greater, indeed, than that which occurs in the usual operation on the non-adherent tonsil.

The question of the disposition of the other tonsil is a delicate one. I have always removed it; and though eugenic reasons undoubtedly might be advanced against it, I have yet to see any untoward results that would lead me to change my belief in its safety.

The results of the operation are particularly gratifying, especially to the patient. All the local symptoms subside with surprising rapidity, so that on the day following operation, the sore throat of tonsillectomy alone remains. Strangely enough, this last symptom is always quite mild on the side of the abscess, and patients invariably remark upon the fact. The lessened sensibility of the wound is probably due to the infiltrated condition of the tissues.

the matters of differential diagnosis and in estimating the results of antisymphilitic therapy. Prognostic importance has been assigned to the count by many investigators when subjecting patients to treatment by mercury, salvarsan or salvarsanized serum, that is, in general it has seemed a hopeful sign when the cell count has dropped. For this reason it seems well to consider the variation in the count in untreated as well as in treated cases. Mitchell, Darling and Newcomb published a study of the cell count in a group of parietic patients in the *Journal of Nervous and Mental Diseases* (November, 1914), showing that there was a general, though not absolute, tendency for the cell count to fall toward the termination of the disease in death.

The present study consists in interval cell counts in cases diagnosed as general paresis or cerebrospinal syphilis (assuming that it is not always possible to make the differential diagnosis) in a series of 46 cases. Treatment consisting of mercury, salvarsan intravenously and potassium iodide was given in 19, the other 27 cases receiving no treatment. The counts were made at varying intervals, some short and some longer. The counts were made in the cell chamber of Fuchs-Rosenthal, staining with Unna's polychrome methylene blue in the pipette. Other tests were also performed on these fluids, to wit: Nonne-Apel test for globulin, Mestrezat test for albumin, Lange's gold sol test, and the Wassermann reaction.

Before considering the actual findings it may be well to speak of the meaning of a pleocytosis. It seems safe to state that the cells in the spinal fluid came from either the meninges, the perivascular or perilymphatic spaces (the probabilities being that it is chiefly from the former). It does not behoove us to consider whether these cells are derived originally from the blood stream entirely or from the vessel wall or meninges: it is sufficient to know that their presence in the fluid speaks for their presence in these places. It is not known what causes them to be cast off into the fluid. As a general rule the exudation of cells is greater in cerebrospinal syphilis than in general paresis, as is seen histologically, but this does not necessarily mean that they are to be found in greater number in the fluid, for there are undoubted cases of paresis showing high counts, and cases of cerebrospinal syphilis showing comparatively low counts. Thus in one case of cerebrospinal syphilis confirmed histopathologically, the count was 109 per c.mm., while in a case of general paresis at one time the count was 310 (Case 3), and in another case diagnosed cerebrospinal syphilis on account of the clearing up of the fluid under mercurial therapy the highest count before and during treatment was 92 per c.mm. It is seen also that the number of cells may jump from 92 to 261 and again fall without treatment (M. M., No. I, 23), and from 80 to 332 (T. F., No. II, 7). From these facts it is seen that the cell count has

VII.

THE SIGNIFICANCE OF CHANGES IN CELLULAR CONTENT OF CEREBROSPINAL FLUID IN NEURO- SYPHILIS.*

BY HARRY C. SOLOMON, M.D., BOSTON,

Assistant Physician, Psychopathic Hospital,

AND

HILMAR O. KOEFOD, B.S., BOSTON,

Intern, Psychopathic Hospital.

THE cell count of the spinal fluid has been used to a great extent in studying cases of syphilis of the central nervous system, especially in

* Being S. I. B. Contribution whole number 128 (1915, 31).
(Bibliographical Note.—The previous contribution was by Harry C. Solomon, H. O. Koefod and E. S. Wells, entitled "Diagnostic Value of Lange's Gold Sol Test," *Boston Medical and Surgical Journal*, Dec. 22, 1915, Vol. clxviii, No. 26, p. 959.

no distinct importance in the differentiation of cerebrospinal syphilis and general paresis.

The report of Mitchell and his co-workers above mentioned, suggests the problem of judging the age of the process or the approach of the terminal stage. Our material consisted for the most part of comparatively early cases, but in these there was so great a variation in the number of cells found in different cases without regard to the stage of the disease that it seemed that no conclusions could be drawn in this question. But from our pathological knowledge we know that cases of "galloping paresis" may show considerable infiltration and comparatively low count in the fluid, and further that slow chronic cases may at any time show active manifestations pointing to marked increase in the meningitis and perivascular infiltration. Further, it must be remembered that some cases in which the inflammatory process is slight, but the parenchymatous degeneration progressive, may go for a long period of years without much change in symptoms and a low count, as shown in the case of G. R. (see below). It is more probably true that the cell count is some indication of the amount of inflammatory reaction present, and thus only in a slight measure an index of the severity of the process, and in very little degree of prognostic value, for in paresis the important changes are of an atrophic nature in the parenchymatous structure.*

Alzheimer has suggested that the parietic process is best indicated by the amount of dementia and that the irritative phenomena, excitements, etc., are an indication of the amount of inflammatory reaction present, and that remissions indicate a partial cessation of the inflammatory process, but in no way an index of the amount of atrophy. If this is so, one would expect a comparatively low count in the remissions. This is not borne out by our meagre figures on the cases showing remissions. On the other hand, the amount of excitement in no way parallels the cell count.

The following tables indicate the data from which our conclusions are drawn:

TABLE I.

CASES HAVING RECEIVED TREATMENT.

A. General Paresis.

CASE 1. J. S. (3998).

Dec. 18, 1914,	16	3 intravenous injections neosalvarsan.
Jan. 6, 1915,	14	2 intravenous injections neosalvarsan.
Jan. 13, 1915,	3	2 intravenous injections neosalvarsan.
Jan. 31, 1915,	4	3 intravenous injections salvarsan.
Mar. 4, 1915,	3	4 intravenous injections salvarsan.

*It may be added here that Head and Fearnside, Fildes and McIntosh state that the reaction of the spinal fluid is an indication more of the conditions existing in the spinal cord region than in the cranial cavity, which, if true, would mean that the cell count has little or no prognostic value in paresis.

During treatment patient became more demented and finally bedridden, due to weakness of legs. No change in Wassermann reaction, globulin or albumin content of fluid, or gold sol.

CASE 2. A. D. (3627)

June 24, 1914,	41	11 intravenous injections salvarsan.
Oct. 6, 1914,	149	
Nov. 11, 1914,	82	15 grs. mercury salicylate intramuscularly.
Dec. 12, 1914,	157	
Jan. 9, 1915,	41	

Patient slightly more aphasic, otherwise condition practically unchanged. No change in other spinal fluid tests.

CASE 3. W. R. (1659).

Sept. 15, 1913,	165	
Oct. 25, 1913,	310	3 intravenous and 3 intraspinal treatments.
Jan. 31, 1914	11	
Feb. 3, 1914,	25	1 intravenous and 1 intraspinal treatment.
Mar. 27, 1914,	77	
April 4, 1914,	23	2 intravenous and 2 intraspinal treatments.
May 14, 1914,	25	
Dec. 1, 1914,	30	1 intravenous treatment.
May 23, 1915,	41	
		3 intravenous treatments.
		17 intravenous treatments, last treatment July 25, 1915.

Patient became progressively worse. No change in other spinal fluid tests.

CASE 4. F. L. (4161).

Jan. 13, 1915,	80	No treatment.
Feb. 3, 1915,	124	
Mar. 12, 1915,	92	3 intravenous injections salvarsan.
April 3, 1915,	37	
April 21, 1915,	22	4 intravenous injections salvarsan.
		2 grs. mercury salicylate intramuscularly.

Patient showed remission of mental symptoms; no changes in spinal fluid except cell count. Patient at first much agitated and quite active, with marked tremors and unsteadiness, these symptoms becoming less as cell count fell.

CASE 5. F. A. (4095).

Jan. 6, 1915,	130	2 intravenous injections neosalvarsan.
Jan. 17, 1915,	56	
Jan. 31, 1915,	15	1 intravenous injection neosalvarsan.
Mar. 4, 1915,	8	
April 7, 1915,	6	2 intravenous injections salvarsan.
		1 gr. mercury salicylate intramuscularly.
		9 intravenous injections salvarsan.

Patient showed remission of mental symptoms, but no change in spinal fluid except cell count.

During time the cell count was high, patient was very excited and in a manic condition; these symptoms of mania subsiding synchronously with fall in cell count.

CASE 6. J. M. (4453).

Mar. 6, 1915,	42	} 3 intravenous injections salvarsan.
Mar. 24, 1915,	23	
Mar. 31, 1915,	12	
April 14, 1915,	14	} 4 intravenous injections salvarsan.
April 21, 1915,	10	
April 24, 1915,	7	
May 1, 1915,	9	} 2 intravenous injections salvarsan.
May 5, 1915,	7	
May 15, 1915,	3	
June 23, 1915,	20	} No treatment.
July 10, 1915,	26	
Aug. 10, 1915,	150	
Sept. 2, 1915,	200	} 4 intravenous injections salvarsan.

Patient continues in maniacal condition. No changes in spinal fluid findings other than in cell count. Note rise in count during treatment. Physical and mental condition worse.

CASE 7. L. Mc. (2758).

June 13, 1914,	8	} 6 intravenous injections salvarsan.
July 1, 1914,	25	

Patient showed practically no mental symptoms. No change in fluid other than cell count.

CASE 8. W. D. (2509).

April 28, 1914,	121	} 3 intravenous injections salvarsan.
June 30, 1914,	140	
July 20, 1914,	30	

During interval in which cell count rose from 121 to 140, patient's condition changed from marked excitement to mental normality. Fluid showed no changes other than cell count.

CASE 9. A. D. (4383).

Jan. 17, 1914,	82	} 2 intravenous injections salvarsan.
April 20, 1914,	225	
April 31, 1914,	37	
April 3, 1915,	158	} 5 intravenous injections salvarsan.
May 25, 1915,	63	

During these 16 months, patient's condition showed slight increase in dementia; no other changes. No spinal fluid changes other than cell count. Note rise in count after cessation of treatment, followed by fall.

CASE 10. M. K. (4654).

April 15, 1915,	80	} 1 intravenous injection salvarsan.
April 24, 1915,	61	
May 1, 1915,	37	
May 5, 1915,	14	} 3 intravenous injections salvarsan.
May 26, 1915,	5	
June 5, 1915,	6	

No change in other findings. Clinical improvement.

CASE 11. A. McL. (4733).

April 28, 1915,	88	} Intramuscular injections mercury twice a week.
April 1915,	112	
May 3, 1915,	53	

No change in other findings.

CASE 12. D. S. (4884).

May 24, 1915,	15	} 1 intravenous injection salvarsan.
May 30, 1915,	26	
June 15, 1915,	77	

Cessation of epileptiform seizures. Spinal fluid tests unchanged.

B. Juvenile Neurosyphilis.

CASE 13. G. U. (4154).

Jan. 13, 1915,	44	} 7 intravenous injections salvarsan.
Mar. 24, 1915,	8	
May 5, 1915,	13	
June 5, 1915,	20	} 3 intramuscular injections mercury.

Very little, if any, change in patient's condition. Spinal fluid findings other than cell count unchanged.

CASE 14. F. A.

April 3, 1915,	4	} 5 intravenous injections salvarsan.
April 28, 1915,	15	

Slight improvement in patient's condition. No change in fluid findings other than cell count.

C. Cerebrospinal Syphilis.

CASE 15. J. R. (2251).

Feb. 13, 1914,	26	} 3 intravenous injections salvarsan.
Mar. 27, 1914,	4	
April 2, 1914,	21	} 3 intravenous injections salvarsan.
May 9, 1914,	4	

Clinical recovery. All signs in spinal fluid became practically normal.

CASE 16. C. S. (4508).

Mar. 22, 1915,	80	} Intramuscular injections mercury.
Mar. 24, 1915,	91	
Mar. 31, 1915,	92	
April 7, 1915,	67	
May 5, 1915,	8	
June 2, 1915,	67	
Aug. 13, 1915,	5	

Clinical improvement. Spinal fluid practically normal on June 2, 1915, except for pleocytosis. Note that pleocytosis is last spinal fluid abnormality to disappear.

CASE 17. A. W. (4517).

Mar. 22, 1915,	75	} 1 intramuscular injection mercury.
Mar. 24, 1915,	56	
May 1, 1915,	9	} 5 intravenous injections salvarsan.
May 22, 1915,	2	
May 26, 1915,	2	} 1 intravenous injection salvarsan.
June 5, 1915,	7	

During interval in which cell count dropped from 56 to 9, patient had apoplecticiform seizure with hemiparesis, with marked excitement following. Since quiet. Wassermann reaction less strong than earlier.

II. UNTREATED CASES.

CASE 1. J. C. (3446).

Sept. 9, 1914,	16	
Oct. 6, 1914,	19	
Oct. 15, 1914,	28	Slow progressive dementia.
Oct. 24, 1914,	25	
May 22, 1915,	28	

CASE 2. C. C. (3931, 3868).

Dec. 2, 1914,	10	} Slowly developing tabo-paresis.
Dec. 12, 1914,	12	

CASE 3. J. C. (3857).

Nov. 18, 1914,	38	
Nov. 28, 1914,	46	} Marked tremor. Demented.
Dec. 9, 1914,	43	
May 24, 1915,	15	

CASE 4. F. D.

Oct. 28, 1914,	20	
Nov. 7, 1914,	25	

CASE 5. M. D. (4179, 4055).

Jan. 17, 1915,	33	} Slowly developing tabo-paresis, advanced stage.
Feb. 3, 1915,	25	
May 22, 1915,	9	

CASE 18. H. S. (4794, 5105).

July 6, 1915,	176	} 1 intravenous injection salvarsan.
July 10, 1915,	347	
July 14, 1915,	69	} 1 gr. mercury salicylate intramuscularly.
July 21, 1915,	85	
July 28, 1915,	81	} 3 grs. mercury salicylate intramuscularly.
Aug. 10, 1915,	20	
Sept. 2, 1915,	20	} 11½ grs. mercury salicylate intramuscularly.
		} 3 intravenous injections salvarsan.

The following conclusions seem justified:—

1. The number of cells found in the fluid of untreated cases offers no definite information of prognostic value.

2. That one is not justified in drawing any conclusions as to whether the case is C. S. S. or G. P., nor the time the process has been active, nor the severity of it, from the cell count.

3. The cell count may vary greatly from month to month, or when the interval is but several days, while at other times it may remain very nearly the same after an interval of months.

4. Cases showing natural remissions may show no reduction in the cell count, or other spinal fluid findings.

5. Cases treated with salvarsan either intraspinously or intravenously tend to show a more or less rapid fall in the cell count. This count will as a rule remain low during treatment, but is likely to rise when treatment has been discontinued, but may rise during treatment after having first fallen.

6. Cases may show remissions during treatment and still have a pleocytosis.

7. Treated cases having the cell count fall to normal may at the same time become very much worse and develop more marked paralytic symptoms.

8. In general paresis the cell count in no way parallels the other spinal fluid findings.

9. In cases in which the *other* tests show an improvement, for instance C.S.S., the cell count also readily and early drops to normal. At times it may drop to normal before other spinal fluid tests become negative; again it may be last to reach normal.

10. The *change* in cell count seen in syphilitic disease untreated, is also found in non-syphilitic diseases, as brain tumor.

11. The cell count offers *nothing* of prognostic importance in syphilis of the nervous system, unless accompanied by improvement of the other laboratory signs.

11. The cell count is not an index to the predominance of irritative or degenerative changes.

(Series concluded in next volume.)

Society Report.

THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

MEETING OF WEDNESDAY, JUNE 2ND, 1915 AT 8 P. M.

The President, DR. JAMES C. WILSON, in the Chair.

RUPTURE OF PORTAL VEIN CAUSING INTRA-HEPATIC HEMATOMA SIMULATING RUPTURE OF A HOLLOW VISCUS.

DR. JOHN B. ROBERTS: A man who fell across a step in the street and struck the upper portion of the abdomen, suffering from great pain, was supposed to have ruptured stomach or intestine, and was operated upon by me a few weeks ago. The operation showed some free blood in the peritoneal cavity, blood in the gastrohepatic omentum and in the neighborhood of the pancreas. No bleeding point was found needing control by ligature. The abdomen was, therefore closed. Death, either from shock or ether poisoning, occurred just as the operation was completed. Post-mortem examination showed a large clot within the liver due to a rupture of one of the branches of the portal vein, or of the portal vein itself just within the capsule of the liver.

PELVIC HORSE-SHOE KIDNEY SIMULATING PERFORATIVE APPENDICITIS.

DR. JOHN B. ROBERTS: In February last, operation was performed for what was supposed to be acute perforating appendicitis with adhesion of the ruptured appendix to the anterior belly wall. The operation was done hurriedly under antiseptic treatment of the skin, and mild appendicitis found without perforation. The swelling which led to the belief that perforation with anterior adhesion of the appendix had occurred was found to be a horse-shoe kidney, the right portion of which lay immediately under the appendix across the spine near the sacral promontory. The right and left portions were connected by a fibrous band uniting the lower poles in this unusual position.

These cases and others show the value of the surgeon's doubting tendency before operating. Though no harm was done by operating, the diagnosis in both these cases was erroneous. Surgeons need a doubting mind because the tendency to jump at conclusions and hastily operate sometimes subjects patients in abdominal, fracture, and other departments of surgery to unnecessary risk.

A few instances of this kind were given to show the truth of this statement.

CERTAIN SYPHILITIC AFFECTIONS OF THE HEART AND AORTA.

DR. J. M. ANDERS: The advent of the Wassermann reaction has shown that the etiologic rôle of syphilis in diseases of the cardiovascular system has been heretofore underestimated. While I would not say with recent investigators that syphilis is the principal factor in the production of heart disease, it can be assumed that rheumatism and syphilis head the list as causes of organic injury to this organ. While the cardiac lesions caused by the spirocheta pallida are usually considered as belonging to the tertiary stage of syphilis, Grassman, Brooks and other investigators have expressed the opinion that serious damage may occur as early as the forepart of the second stage. Aortic and cardiac syphilis may be the result of hereditary lues. The claim made by Landois, Citron, Hausmann, Sears and others that lues may affect the heart alone is interesting and important. In two infants who died, one at three months of inanition, the other at eight days of asphyxia, Warthin and Snyder found the spirocheta pallida in the heart muscle, while neither histological lesions nor spirochetæ were found elsewhere.

Among the commonest cardio-vascular conditions due to syphilis are myocarditis, aortic regurgitation, angina pectoris, and mesoarteritis often resulting in aneurysm. Mesoarteritis with or without coronary changes is commonly the primary complaint in cases in which, as frequently occurs, two or more of the above named affections are found in association. That this condition is due in many cases to syphilis, has been demonstrated both by post-mortem evidence and by the results of carefully conducted therapeutic observations. The intimate connection between lues and aneurysm, well-known to the older writers has been emphasized by those of modern times. With Hausmann, however, I would caution the medical profession against regarding every case of aneurysm, even in syphilitic subjects, as due to lues. Two differentiating etiological factors are that the root of the aorta is the usual seat of luetic aneurysms, which are frequently multiple.

Syphilis is now generally regarded as an essential factor in the causation of aortic incompetency, more particularly in cases developing before the 45th year of life. As in aneurysm, a positive Wassermann reaction alone, unsupported by clinical evidence, does not warrant an assured diagnosis of lues, although it renders highly probable the existence of syphilis. On the other hand, it must be remembered that aortic incompetency in a luetic subject may be due to other causes, especially if the lesion develop after middle life.

Early involvement of the myocardium is not infrequent in the course of syphilis. Early recognition is difficult but important. The symptoms do not differ from those of myocarditis due to other infections and it has been shown that they disappear

promptly under energetic antisyphilitic treatment. Anginoid pains are occasionally present, and obliterative endarteritis implicating the coronaries and producing myocarditis may result in attacks of true angina pectoris. Although a positive or negative Wassermann test is not an absolute criterion, Brooks contends that it is better than the 70% of error based on the history or clinical findings alone.

Of angina pectoris, I have collected 270 cases from the literature, of which only 72, or 26.5%, gave evidence of syphilis. This percentage is much too small, since in 250 of the cases no mention was made of a Wassermann test. The close association of syphilis and angina is amply confirmed by modern authorities.

My discussion of the treatment of cardio-vascular syphilis will be limited to prophylaxis. Doubtless the incidence of cardio-vascular disease would be much lessened by a more systematic and vigorous treatment of luetic infection in general. Physicians should feel the serious responsibility of the treatment of early syphilis in the wisest manner possible. This is further emphasized in the hazard of administering salvarsan or neosalvarsan in the severer forms of cardio-vascular syphilis. It has been found that death, occurring suddenly or after several days from the use of these agents, is commonly due to myocardial degeneration secondary to coronary lesions.

DISCUSSION.

DR. GEORGE W. NORRIS: I agree with Dr. Anders that since the discovery of the spirocheta pallida and our knowledge of the Wassermann test we have learned to recognize a number of lesions definitely syphilitic which in the past we barely suspected. In the last year more attention has been given to syphilitic nephritis, and it is somewhat comforting to know that if we do give mercury or salvarsan to these patients, we are likely to benefit their nephritis rather than to injure the kidneys. One point to which I would allude, emphasized by Dr. Anders, is the frequency with which sudden death may occur in syphilitic myocarditis. Among the symptoms which have struck me as having some guiding value are low pressure, mild anginoid attacks associated with dilatation of the left ventricle, and, as Dr. Anders has emphasized, cardiac irregularity followed by auricular fibrillation. In such cases salvarsan must not be administered without due consideration. I am particularly interested also in the question of aortitis in the young. In a considerable percentage of newborn infants dying shortly after birth the presence of the spirocheta pallida has been noted in the aorta. I feel that syphilis is inadequately treated in our dispensaries. Hospitals which refuse to treat this disease in its early stages are perfectly willing to give aid when the patient returns at a practically incurable stage. It seems to me that more efficient treatment of syphilis in dispensaries is one of the crying needs of our medical work today.

DR. JAMES TYSON: In my experience as a young man in dispensary service our method of treating cases which included rheumatoid affections was to give first iodide of potassium. Failing with this we added mercurial bichloride and an astonishingly large number of cases were benefited. It would seem, therefore, that the new methods of treatment confirm the old ones. I have sometimes thought that although this was a rough and ready method of

treating symptoms we might perhaps adhere to it with advantage a little more frequently than we do in modern times.

CLOSING DISCUSSION.

DR. ANDERS: I was glad to hear Dr. Norris say that we could employ salvarsan and mercury in nephritis due to syphilis. I have seen several very remarkable results in such instances from the alternate, and also from the separate use of these two agents. We must, however, be very certain that the syphilis is the real cause of the cardio-vascular and renal conditions. Mercury has its selective affinity for the kidneys, and there is no other variety of nephritis than the syphilitic in which its use is justified. While it is true that since the discovery of the Wassermann reaction the true importance of syphilis as a factor in many heart diseases has been in great part established, this cannot be said of this test in relation to angina pectoris. The close association of angina pectoris and syphilis remains to be established, according to my figures, at all events; but I believe it will be, once the profession is alive to the importance of making Wassermann tests in all cases of angina pectoris. Neglect to examine the heart systematically in the early stages of syphilis is attended with untoward results in many cases. In at least one-half of these cases symptoms arise which should arouse suspicion of cardiac involvement and lead to the most vigorous antisyphilitic treatment. In regard to cardiac involvement in the course of syphilis, the words of John Locke truly apply: "Prevention is better than cure, and far cheaper."

PAPER OF DR. GEORGE C. SHATTUCK.

(Lady Paget Hospital.)

CLINICAL OBSERVATIONS ON TYPHUS FEVER IN SERBIA.

Among several hundred cases of infectious fever, about fifty-three were found to have true typhus fever. The following observations were based upon this series.

Among the clinical signs the rash is undoubtedly the most important. It is rarely seen on the face. Dr. Sellards, however, saw one case with an extensive eruption which covered the entire face. Within twenty-four to forty-eight hours the rash extends over the trunk and extremities. At first it is rose-

pink in color and slightly elevated, but it presses out completely. After a day or two the spots become redder, then they darken, become livid, and cease to press out completely. In the severer cases on fading they leave dark, pigmented brownish areas. In the mild cases the rash may fade before it reaches the darker, hemorrhagic form. The spots vary in size from the diameter of a pin head to that of a pea, and they have irregular faded margins.

A flushing of the face is likewise very characteristic and varies in its distribution. This later assumes a dusky, cyanotic color.

A slight stiffness of the neck is found in the majority of the cases. At times this is very pronounced. A Kernig's sign may be present on one or both sides. This is slight at times and again it is marked.

Muscle sensitiveness is quite common. The extreme sensitiveness of the calves described by many did not form a prominent feature here. Where the cases are extremely sick the whole muscular system frequently becomes sensitive.

Due to the difficulties with the language and the condition of collapse of many of the patients on admission, a perfectly satisfactory examination of the spleen was impossible. Usually the area of splenic dullness was enlarged.

The throat manifestations are very interesting. Sordes appear soon and the mouth becomes very foul. The mucous membranes of the mouth and pharynx become reddened early. As the disease advances the mucus becomes dried and more viscid.

Bronchitis is as frequent as in typhoid. On the whole the respiratory symptoms here are more prominent and severe than in typhoid. The picture may closely resemble pneumonia. In some cases the respiratory rate rises to thirty or forty. The lung signs, however, remain relatively slight as a rule. Cough is a fairly constant symptom.

Circulatory weakness is extremely common. But the pulse and the temperature show no constant relation. In the sicker cases the blood pressure drops to a low mark. The pulse pressure is then likewise low and the pulse feels weak, irregular, and thready. A dicrotic pulse was not common in this group.

As a rule the gastrointestinal symptoms are not prominent. Delirium varies in kind and in degree. Some have the low muttering type with tremor; others have delusion; and again others show the violent variety similar to the alcoholic delirium.

The three main types of typhus which were noticeable in this epidemic were:

1. *The asthenic form* in which the patient lies on his back in a semiconscious condition, breathing through his mouth. There is marked emaciation with weakness.

2. *The respiratory form*. Such patients appear to have pneumonia.

3. *The comatose form*. Coma is the prominent feature here and suggests the uremic state.

The complications are very various. In the wake of the dirty mouth a middle ear infection or parotid gland infection, or an ulcerated throat may appear. Bed sores are very difficult to avoid even with competent nursing. Abscesses are common and pneumonia is moderately common. A frequent complication of the face is herpes. Gangrene, which is rare in most infectious disease, is common in typhus. It appears especially on the nose, cheeks and feet. It is rarely seen except in cold weather.

PAPER OF DR. A. W. SELLARDS.

(Lady Paget Hospital and the Military Hospital in Belgrade.)

THE MODE OF TRANSMISSION AND THE ETIOLOGY OF TYPHUS FEVER.

One may fairly safely venture into the midst of an unknown infectious disease if certain important precautions be observed. Measures must be adopted against contact with insects and against droplet infection. The water and food supply, in addition, should be above suspicion. As a knowledge of the mode of transmission of this disease is still in dispute, so far as certain details are concerned, it was necessary for the members of the commission who studied in Serbia to observe all these precautions.

A one-piece garment extending from the toes to the neck with attached gloves was usually worn next to the skin. This, as a rule, was covered with the customary hospital gown and shoes. The hair was clipped short. A surgeon's cap and face mask completed the outfit. This form of dress was necessary as the great number of new patients prevented the adoption of successful measures against lice. The Austrian prisoners, however, were very conscientious in their efforts to keep the premises lousefree.

As the living quarters were clean of insects the uniforms were removed on leaving the wards. After each visit the suits were sterilized,—usually with chloroform vapor overnight.

The evidence in support of the louse mode of transmission is still incomplete in certain respects. Nicolle, Anderson and Goldberger, and Ricketts and Wilder have all satisfied themselves that the louse is capable of transmitting the disease. The criteria of each set of observers, however, are not accepted by the others. Nicolle found a rise in temperature in his feeding experiments but encountered no true immunity. Ricketts and Wilder, on the other hand, saw no rise in temperature. All of their animals had immunity. They regard all monkeys as susceptible to typhus. Anderson and Goldberger found much immunity among their monkeys.

The virus of typhus, according to Nicolle, passes through a definite cycle. The louse is its host for about seven to nine days. Ricketts, however, found that subsequent to the first week after feeding lice with the virus of typhus they remained infectious as long as they lived. It is the belief of all workers in this field that the disease does not spread as a single direct transmission.

There have been a few human experiments recorded. Two of Nicolle's assistants were accidentally bitten by infected lice. Neither developed typhus. Recently some notes have been published about a gardener in a foreign jail who dropped some lice infected with the disease down a prisoner's neck. In ten days the prisoner developed typhus fever.

Though the louse may furnish the common mode of transmission, other avenues of infection may exist. Droplet infection requires some further consideration.

Concerning the etiology, typhus falls among the acute exanthemata in many respects. From its clinical symptoms, typhus would not appear to be a protozoan disease.

Demonstration of scenes in Serbia with the reflectoscope.

DISCUSSION.

DR. STRONG: The most striking features of the Serbian epidemic were the high percentage of pharyngitis and laryngitis, the high percentage of the complication gangrene, and the high mortality. Three members of our commission who devoted their time to the study of the etiology of typhus in association with a worker from the British unit and one from the French unit were all unable to confirm the findings of Plotz. It has recently been confirmed that the blood of typhus patients is sterile,—a differential point from typhoid.

DR. CHRISTIAN: In America we have had some experience with typhus fever. There is a bronze tablet over a railroad bridge in Montreal which commemorates the death of several hundred people in an epidemic of this disease during its construction. Epidemics have also visited Sparrows' Point, Maryland, and New York City.

DR. F. C. SHATTUCK: Where we hear about the details of typhus from the lips of those who have just been in Serbia, it becomes clear why typhoid and typhus so often travel together.

DR. STRONG: The whole question of the etiology is still an open one. We should have a commission appointed to study typhus.

ERNEST G. GREY, M.D., *Secretary.*

RENAL PATHOLOGY AND THERAPEUTICS.*

ACIDOSIS.

DR. F. W. PEABODY. Few subjects at present are receiving more attention than that of acidosis; and its frequent occurrence in children, its great importance in diabetes and its occurrence in chronic nephritis make acidosis a subject that should be well understood. Acidosis does not mean an actual change in the reaction of the body fluids, for their reaction is remarkably constant. The mechanism to prevent acid accumulation or a change in the blood reaction acts in four different ways:

- (1) The large supply of bases in the body tissues may be drawn upon.
- (2) Kidney excretion *e.g.* phosphoric acid.
- (3) Lungs— CO_2 is removed.
- (4) Changes may take place in blood composition to neutralize acid.

If we consider the blood as a mixture of volatile and non-volatile acids with a definite limit to total acidity, it becomes plain that an increase in the amount of non-volatile acid takes place at the expense of the volatile CO_2 . Thus the CO_2 the blood can carry decreases as the non-volatile acid increases and the CO_2 in the blood becomes an index of the formation of acidosis.

The dyspnoea of chronic nephritis is related to acidosis, but not solely due to it. Patients with chronic nephritis are more susceptible to CO_2 in inspired air and to other causes of dyspnoea. But the periodic respiration of advanced chronic nephritis, more or less distinctly Cheyne-Stokes in type, is

probably due not to simple acidosis but to changes in the respiratory center. There is a hypo-excitability of the respiratory center, which is interrupted by periods of increased excitability.

DR. CHANNING FROTHINGHAM, JR.: The tests of renal function here considered concern themselves with the function of the removal of water salts and the products of metabolism, and not with any internal secretion which the kidney may have.

In the past various tests have been used, since to be abandoned. Among these are cryoscopy, the electrical conductive power of urine, the excretion methylene blue, rosaniline, phloridzin, lactose and K1.

At present the following tests of renal function are employed:

- (a) The relation of urine output to fluid intake.
- (b) Salt excretion compared with salt ingestion.
- (c) Nitrogen excretion compared with nitrogen ingestion.

The above three must be studied in 24° specimens, and in (b) especially exact knowledge of the intake is requisite.

- (d) The excretion both as regards promptness and amount, of six milligrams of phenolsulphonphthalein injected in solution intramuscularly. Specimens of urine taken one hour and ten minutes after the injection and then again one hour subsequently are made alkaline and their phthalein content is estimated by calorimetric means. The two-hour total is probably more important than the relation of the first and second hours' production, so that usually only one specimen is taken at the end of two hours and ten minutes. Fifty per cent. excretion is a good standard to take as a minimal normal for the two-hour specimen.

The two qualifications of this test are that it is not a good diagnostic sign in early chronic nephritis, and it may be present as the result of mere passive congestion.

- (e) Incoagulable protein in the blood as shown by method of Folin and Dennis. Below 30 mg. in 100 c.c. is normal incoagulable protein. Over 50 mg. would make the prognosis grave. Between 30-50 mg. of incoagulable protein have been found in acute infections, or where chronic nephritis could not be proved, but above 30 is ordinarily pathological. High nitrogenous diet may greatly increase incoagulable protein in cases with nephritis, so patient's diet must be known.
- (f) Schlayer's test, which is positive when a patient who has been on a known salt intake for four to five days fails to excrete 10 gms. of added salt in 48 hours. Frequently salt excretion doesn't increase at all. This test is positive early in the course of nephritis but doesn't increase after a certain point is reached. Experience at the Peter Bent Brigham clinic indicates that sodium retention is found in chronic nephritis generally and is not limited to one type.
- (g) Monakow's test, which is positive when a patient who has been on a known diet fails to excrete 20 gms. of urea (10 gm. of added N) in 48 hours. This is not a valuable test for the early stages of the disease.

* Lectures at the Harvard Medical School on Dec. 17, 1915.

- (h) Hedinger and Schlayer's test, in which on a known intake of NaCl, N and water in five known and varying meals the excretions of these substances are studied in two-hourly samples (plus one night sample). The normal kidney in these periods should excrete different amounts of urine, different amounts of salt and nitrogen and at different concentrations.
- (i) The Ambard test of the concentration of salt and nitrogen in the urine of a 2^d period as compared with the concentration of the same substances in the blood taken at the middle of this period. This has been worked out by McClean as a formula giving numerical index expressing the relation between the urea nitrogen and salt of the blood and urine. Van Slyke's method of determining urea with urease is the simplest way to study nitrogen excretion.

DR. HENRY A. CHRISTIAN: Tests of renal function constitute one of the most valuable procedures in the care of chronic nephritis, and certain of these tests are applicable without the complete laboratory equipment of a large hospital.

(1) Phthalein test gives valuable information and requires only a few test tubes, a 1000 c.c. flask and a hypodermic syringe. The phthalein comes in ampoules ready for injection, and one of these may easily be diluted to 50, 40, 30, 20 and 10 per cent. solutions, stoppered and kept for future calorimetric readings.

(2) The Hedinger and Schlayer diet has been modified for use at the Peter Bent Brigham Hospital. It depends on there being approximately the same amount and same sort of food each day with a known fluid intake. The amounts of fluid in each two-hour collection are important, especially the night specimen (normally about 400 c.c. on a 2000 c.c. 24^h intake) and the specific gravity of the different two-hour specimens shows how promptly and how adequately the kidney can concentrate its solids.

The salt should be quantitated absolutely and by its percentage, thereby affording an idea of the kidney's ability to handle salt and of the amounts to give in the diet.

It is not worth while to quantitate the nitrogen ordinarily, for knowledge of amount and specific gravity of urine, and amount and concentration of salt give the most important data in estimating renal function.

The Management of Cases of Chronic Nephritis.

- (1) Patients with hematuria should be rested in bed for two to three weeks. If hematuria does not stop, patient should get up and get some exercise to avoid loss of muscular tone and discouragement.
- (2) Chronic nephritis with hypertension should always be rested to prevent cardiac decompensation. Oedematous patients also should rest.
- (3) No prolonged cold baths should be taken, and especial care against chilling should be taken after two hot baths or sweats per week.
- (4) The cathartics often are used too much. Oedema, and definite uremic or toxic symptoms are the only conditions calling for marked watery catharsis. Vegetable cathartics occasionally are valuable to prevent salt

storage. Calomel is probably contraindicated.

- (5) Presence of oedema indicates that a marked reduction should be made in fluid intake. Hypertension indicates simply that some reduction should be made. Watch the ratio, 1500 output, 2000 intake, and cut down fluids if they are not well excreted.
- (6) Cut down salt in presence of oedema, or where it is inadequately excreted.
- (7) Diet. Eight hundred c.c. of milk, in acute conditions, but milk is too high in protein and salts, to constitute sole diet of larger caloric value. Use starchy food instead, use one or two eggs and one slice of meat (except salt meat) at another meal, and as much vegetables as patient wants. Cut out meat and eggs one day a week, and all alcohol. Tobacco, tea and coffee may be left in.
- (8) Diuretics put increased work on the kidneys, and if renal function be below a certain level, diuretics are ineffective. Oedema is the chief indication. Theocin is probably the best diuretic with a competent kidney. Caffein and theobromin-sodium-salicylate may be effective, differing often in which is the more effective. Sodium citrate is not a diuretic without water.

A. GREGG, A.B.

Book Reviews.

The Clinics of John B. Murphy, M.D. At Mercy Hospital, Chicago, August and October, 1915. Published bi-monthly. Philadelphia and London: W. B. Saunders Company, 1915.

Both the August and October volumes contain an unusually large number of articles, although the volumes themselves remain the same size; it is, of course, obvious that the articles must necessarily be short. In the August number there are no less than thirty-two headings, practically every one of them including a brief description of an operative procedure. There is a series of cases illustrating surgery of the head, skull and spine, and a considerable number of fracture cases. It is impossible within the short space to enumerate even so many different headings. In the October number there are twenty-seven headings, including a talk by Dr. William B. Coley of New York City, upon carcinoma and its treatment with the mixed toxins. Dr. Murphy describes his operation for recurrent luxation of the humerus, and a large number of very complicated fractures, as well as a series of cases illustrating surgery of the chest, kidneys and the joints. The text, photographs, x-rays and cuts continue to be, as they have been in the past, interesting and suggestive.

THE BOSTON Medical and Surgical Journal

An independently owned Journal of Medicine and Surgery, published weekly, under the direction of the Editors and an Advisory Committee, by the BOSTON MEDICAL AND SURGICAL JOURNAL SOCIETY, INC.

THURSDAY, DECEMBER 30, 1915.

EDITORS.

ROBERT M. GREEN, M.D., *Editor-in-Chief.*
GEORGE G. SMITH, M.D., *Assistant Editor.*

WALTER L. BURRAGE, M.D.
FREDERICK T. LORD, M.D. *For the Massachusetts Medical Society.*

COMMITTEE OF CONSULTING EDITORS.

WALTER B. CANNON, M.D.	ALLAN J. MCLACHLIN, M.D.
HARVEY CUSHING, M.D.	ROBERT B. OSGOOD, M.D.
DAVID L. EDSELL, M.D.	MILTON J. ROSENAU, M.D.
REID HUNT, M.D.	EDWARD C. STREETER, M.D.
ROGER I. LEE, M.D.	E. W. TAYLOR, M.D.

ADVISORY COMMITTEE.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States. \$6.56 per year for all foreign countries by *longing to the Postal Union.*

The editor will be in the editorial office daily, except Wednesday and Sunday, from one to two-thirty p. m.

Papers for publication, and all other communications for the Editorial Department, should be addressed to the Editor, 126 Massachusetts Ave., Boston. Notices and other material for the editorial pages must be received not later than noon on the Saturday preceding the date of publication. Orders for reprints must be returned in writing to the printer with the galley proof of papers. The Journal will furnish the first one hundred reprints for half the cost price.

All letters containing business communications, or referring to the publication, subscription, or advertising department of the Journal, should be addressed to

ERNEST GREGORY, *Manager.*

126 Massachusetts Ave., Corner Boylston St., Boston, Massachusetts.

ADMISSION TO THE STATE TUBERCULOSIS SANATORIA.

In spite of circulars of information which have been sent at various times to every physician in the commonwealth, there seems still to be considerable misunderstanding as to exactly what class of consumptives the state desires to care for in its four sanatoria.

Since its opening in 1898, the Rutland State Sanatorium has been reserved for patients in the incipient, early and favorable stages of the disease. This has not prevented in the past, nor does it prevent now, the admission of many far advanced cases whose presence helps to defeat the very purpose for which the institution was planned. The admission of such advanced cases was made easy when the filing of applications for this and the other sanatoria was given over to the medical profession of the state at large instead of being confined, as it was prior to 1910,

to a small group of special examiners. In view of this condition of affairs, whereby patients who were classified as incipient on their application blanks were found to be advanced on admission, and were constantly filling up beds at the sanatorium, and also because there was nothing to prevent a patient, who might be an incipient and early case upon entrance, from remaining at the institution indefinitely until he became a far advanced and dying consumptive, the board of trustees has made two important regulations which should be clearly understood by the doctors in this commonwealth.

The first of these was to limit the residence at the Rutland Sanatorium to two years. At the end of this two years' time patients are transferred to another sanatorium or to some local hospital, or elsewhere. This has already had good results in that a fairly large number of chronic cases have been transferred to a more suitable place. It is the intention of the board to reduce this period of stay still further, probably to eighteen months or a year, it being held that if a patient cannot gain or reach an arrested condition in a year or eighteen months, his place should be given over to someone else.

In addition to this and of still greater importance, the board has passed a rule whereby every patient, favorable or unfavorable, entering the institution is placed on trial for a period of one month. If at the end of this month's period of observation he or she is found to be unfit for the purposes for which the institution was planned, the patient is removed to another sanatorium. Although this causes heartburnings on the part of certain patients, it can readily be seen that in the long run it will do much good.

So far the board has applied this rule only to patients who are physically too far advanced or too sick for the Rutland Sanatorium. It is probable, however, that in the future, as the number of local tuberculosis hospitals increases, the line will be drawn tighter and certain patients will be sent away not because they are too sick, but because they are not sick enough. There is a growing tendency in the medical profession of this state, especially in those dispensaries which are designed and planned solely for the diagnosis and treatment of tuberculosis, to advise and urge sanatorium treatment for patients who present signs not of tuberculous disease but of tuberculous infection. The difference between the two

is evident. While such a patient will undoubtedly be benefited by a stay at the sanatorium, even if his signs of active disease may be only of the slightest, it is manifestly not fair to the others urgently in need of treatment for the beds to be kept filled in this way.

The physicians in this state, therefore, are urged to remember that the waiting list for the Rutland Sanatorium is a very long one and to use every care in the selection of cases whom they recommend for this institution.

While at the other three sanatoria at North Reading, Lakeville and Westfield the admission is not by any means limited to patients in the early and incipient stages, it has been deemed advisable, as the result of the experience of the past four or five years, to decline to take patients in the far advanced and progressive stages of the disease. In the year 1910, when these three institutions were first opened, the number of beds in local tuberculosis hospitals was very small. Therefore, rather than let beds in the new institutions lie vacant, they were at once filled up with those patients for whom application was first made and who were urgently in need of treatment. This resulted in the admission of a very large number of far advanced cases and the subsequent unfortunate result that the sanatoria became known as homes for advanced consumptives. Gradually the number of beds in local tuberculosis hospitals has increased and it is hoped that the strain on our state institutions will be diminished. While, therefore, the board of trustees has no hard and fast rule in regard to the admission of far advanced consumptives and in special instances is willing to make exceptions, as a general thing it does not wish to accept this class at the sanatoria. The reasons for this are manifest. These institutions are intended and built to be sanatoria in fact as well as in name. Real sanatorium work cannot be done when the beds are filled with far advanced cases. Of still greater importance, however, is the fact that these far advanced cases in many instances leave the institution and return to their own homes to infect others at the very time when they are most urgently in need of institutional supervision. Physicians therefore are urged to use every means at their disposal to send this class of patients to local tuberculosis hospitals rather than to make application for them to enter a state sanatorium.

A NEW CONSULTATION CLINIC.

THE New Consultation Clinic at the Massachusetts General Hospital, notice of which is given on the last page of this issue of the JOURNAL, is one of the more significant medical events of recent years. Judged by conservative standards, it is an encroachment by the hospital upon the territory of individual physicians; from a more enlightened point of view, it is a further step towards improving the service which the medical profession as a whole renders the public. Whether great oaks will grow from this acorn is a matter of speculation; it may come to treating the population of cities through the medium of hospitals, which seems to us a much better solution of the problems raised by Bernard Shaw in the preface to "The Doctor's Dilemma" than would be found if medicine became a function of the state.

The theory of the clinic is to provide for people "of moderate means" a way of securing for their ills as nearly correct a diagnosis as can be reached by first-class present day methods, and to provide this without pauperizing those who take advantage of it, or forcing them to lie about their financial condition.

Any move as radical and as untried as this, is fair game for criticism, and it is, of course, probable that many of the details will require readjustment. The fee of five dollars, which it is proposed to charge, seems to many to be too small a return for the amount of investigation which will be required by some of those who apply. On the other hand, it may be that many cases sent to the hospital for diagnosis, and now admitted gratis to the regular Out-patient Department, will be honest enough, and indeed will prefer to pay the fee demanded by the afternoon clinic. The prevention of abuse of the privilege will depend upon the care with which physicians select the patients whom they refer.

One point seems clear; there can be no doubt that the Consultation Clinic will benefit the public—the people for whose advantage the profession of medicine was invented. This will not be due to successful individual diagnoses alone; it will follow, later on, that people will demand more accurate diagnoses and the application in their own cases of some of the more scientific diagnostic methods, such as they or their friends have seen employed at the hospital. In this way certain of the fatal results which we now see—the postponement of cystoscopy until the

tumor is beyond treatment, for instance—will be avoided, and the general standards of medical practice will be raised.

That the Clinic will work hardships for the general practitioner seems improbable; he will be aided in his management of the case, and if the disease is one which he is unsuited to treat, the sooner he learns that fact the better for his reputation. If, as is requested in the circular which the Massachusetts General Hospital is sending to physicians, they accompany their patients, the Clinic may come to occupy a very important place in the post-graduate education of the medical profession.

The success of the clinic will depend primarily upon the attitude assumed towards it by the general practitioners of Massachusetts. They can feel sure that the staff of the Massachusetts General Hospital will give satisfaction, and the provisions which are being made, to the end that each consultation will be answered by a personal letter from one of the men who examined the case, insure an intelligent and satisfactory response.

That the Clinic will succeed is not only our sincere wish, but our conviction. The principle is sound; we believe that physicians will be quick to appreciate its advantages, both to their patients and to themselves.

MODERN EUTHANASIA.

THE recent public outburst over a case, in which the life of a defective newborn was not prolonged by an operation for artificial anus, again brings to light the ever-increasing interest of the public in the problems centering around the control of the defective element in society; not that this interest is an entirely new one. It dates from the early Greeks, who exposed their weaklings to the elements to perish, and has come down to us, through all the many methods suggested to overcome racial weakness from overpopulation or otherwise, to the present modern desires to prevent the inception of the defective by prohibiting the mating of defectives, of requiring all prospective mates to undergo physical examination to determine their freedom from disease or defect, or in the more radical procedure of requiring the sterilization of the defective element in society. And whether it is

the exposure of the weak or the sterilization of the defective, they are all euthanasia in principle, since they prevent the coming into being or the further development of human beings, only that the modern method is far more comprehensive than the ancient. The most radical methods of preventing conception are not nearly so successful as surgical sterilization. Indeed, while law prohibits disseminating this knowledge or otherwise actively aiding this end, the legal status of the surgical method of preventing conception has not yet been determined.

In spite of the universally accepted hereditary nature of most defective conditions, little is known of the method or scheme of transmission. It is for this reason that this form of euthanasia by sterilization of defectives is opposed by many scientific and race-proud people. It must be remembered that not all the offspring of known defectives are necessarily defective, nor any, indeed. Dominant and recessive qualities are not blended in the germinal cells into transitional types, and transmitting blends of commensurate inferiority, but they are grouped so that either type in general only may become patent generally, or specially only as to certain qualities. In a series of offspring resulting from the mating of dominant and recessive types, both good and bad may result, with an evolutionary tendency in the predominance of dominant types. If the number of the offspring is small, perhaps only the defective part of the series may be born. This is given as an explanation for the presence of norms or even genius in known defective families.

The question that naturally arises is whether, in sterilizing, it is right to sacrifice the lives-to-be of the possible normals in order to destroy those of the possible abnormal? Practically, this radical procedure would simmer down to the defective inmates of institutions or prisons, and would not reach the larger number of both kinds who are at large and who have, therefore, an unrestricted opportunity for propagating their kind. In some states that have passed sterilization acts, the acts have been declared unconstitutional as being "cruel and unusual punishment." Besides, these laws sanction a form of prevention of conception more radical than the usual methods which are prohibited as against public policy. To sanction this procedure in known defectives would consistently be to sanction it in individuals who, while themselves not defective, come from defective stock, or in indi-

viduals of grossly bad environment and great fecundity. The question is a new one, with scientific knowledge still meagre, and it will, therefore, perhaps be better until more is known about the ethnic tendencies of the human race, to go slowly with radical innovations. Euthanasia and eugenics, in whatever forms, are yet but ideals—perhaps only fetiches.

LIBRARY OF THE HARVARD MEDICAL SCHOOL.

THE report of the librarian of the Harvard Medical School shows a commendable increase in the number of volumes, pamphlets and reprints which have been added to the school libraries. There have been purchased 105 volumes, 388 have been received as gifts and 2000 have been transferred from the Harvard College Library. These, with a number from other sources, make the total number of volumes added for the year to be 3100. Pamphlets and reprints number 11,670, and government publications number 397. The library now includes 27,000 volumes and 46,067 pamphlets. It is interesting in this connection to compare this with other medical libraries in the country. The College of Physicians of Philadelphia contains 105,540 volumes; the New York Academy of Medicine, 100,320; the Boston Medical Library, 83,107; and Johns Hopkins Hospital, 17,000. The attendance has also increased, especially at the Central Library, which now is open for five evenings each week until ten o'clock.

In addition to these volumes, the Library has been presented with a large number of interesting and valuable pictures and manuscripts. Dr. J. T. Bottomley gave several pictures of Boston physicians, and Dr. M. J. Rosenau over one hundred prints of German men of science. Dr. E. H. Bradford, besides presenting the Library with several pictures and an album of photographs of the Massachusetts V. A. A. Hospital Ship "Bay State," contributed a pamphlet by Aaron Dexter, entitled, "Account of a Locked-Jaw. Boston, 1790." A manuscript of a lecture on the "Use of Tobacco," by Benjamin Waterhouse, Cambridge, 1805, was given by Dr. Bowditch. A set of three volumes of manuscript notes of the lectures given by Dr. Francis Minot, was presented by his daughter and grandson. These manuscripts and prints are displayed in

two glass cases presented by the Harvard Medical Alumni Association.

MEDICAL NOTES.

FIRE IN A HOSPITAL.—The Isolation Hospital of Jersey City was seriously damaged by fire on December 15, and only by prompt action on the part of nurses were the twenty-three children who were ill in the building, taken to a place of safety. No one was hurt.

TYPHUS FEVER IN MEXICO.—Report from Mexico City on December 16 states that the epidemic of typhus fever in that city, which was noted in the issue of the JOURNAL for December 16, still continues, but that drastic measures for combating it have been undertaken by General Carranza. A special corps of sanitary police has been organized to undertake the thorough cleaning of all public and private buildings in the capitol and surrounding towns.

"Public baths and barber shops will be established and persons of unclean appearance will be forced to bathe and change their clothing. The fresh clothing will be furnished free by the government. The sale of alcoholic liquors is to be absolutely prohibited, and public places of amusement will be disinfected daily and forced to close at eleven o'clock each night. Uncleanly persons, no matter what their social class, will be denied admission to street cars or other public vehicles. Heavy penalties in fine or imprisonment are to be applied to all who fail to comply with the sanitary orders.

"Up to date thirteen cases of the fever have been registered in the American and English colonies here. Many more cases have been noted in the other foreign colonies. In the aggregate, however, the number of cases in the foreign settlements is infinitesimal compared with the Mexican cases.

"The vigorous measures of the government to combat the disease are meeting with the warm approval of the people. The army is coöperating with city officials, 400 soldiers being detailed to clean barracks, and make the posts sanitary. On Nov. 29 it was estimated there were 11,000 cases of typhus fever in the Federal district and neighboring towns. The death rate exceeded 130 persons a day."

Further report by way of Laredo, Texas, on December 18, states that the total number of cases of typhus fever during the present epidemic is estimated from 20,000 to 60,000.

DRY STREET SWEEPING METHODS.—On December 18, the committee of public health of the New York Academy of Medicine presented a report to that body on the subject of street cleaning systems, and emphatically condemned all meth-

ods of dry sweeping on account of their danger to health. The report recommended the adoption of wet sweeping methods, with adequate flushing to keep the streets as free as possible from dust.

GOATS' MILK FOR INFANT FEEDING.—The weekly bulletin of the New York Department of Health for December 18, 1915, states that a number of medical authorities have advocated the more extensive use of goats' milk for infant feeding, the main reason being the well-known immunity of goats to tuberculosis. In some parts of Italy goats' milk is the common milk of commerce, herds of goats being driven through the streets and milked before the eyes of the customers. So far as the immunity to tuberculosis is concerned, the use of goats' milk in infant feeding is advocated, not alone because of the absence from the milk of tubercle bacilli, but because it has been thought that the milk might perhaps contain immune bodies which would show positive action in preventing tuberculosis or favorably influence the course of a tuberculous infection already established.

An interesting experiment in this connection has recently been undertaken at Sea View Hospital. A herd of twenty-six goats bred by the U. S. Department of Agriculture, mostly of Saanen and Toggenberg stock, has been placed at the disposal of the hospital by the Federal authorities. This permits of the feeding of 125 children. In order to follow the matter intelligently, Dr. E. S. McSweeney, Medical Director of Sea View Hospital, has arranged for the co-operation of the Health Department Research Laboratory. This will enable the hospital authorities to supplement their clinical observations with careful laboratory data.

The outcome of the experiment will be waited with interest. Certainly every means should be employed for reducing tuberculous infections in infancy.

MEDICAL EXAMINATION DAY.—In last week's issue of the JOURNAL we noted the occurrence of medical examination day on December 8.

Medical Examination Day met with a very hearty response on the part of the people of New York City. Although Wednesday, December 8, was designated as Medical Examination Day, many persons called at the various clinics and offices of the Department of Health on Monday and Tuesday. A large number applied for examination yesterday, and everywhere there seemed deep appreciation of the new work which the Department of Health is attempting to inaugurate.

Medical Examination Day has opened up an entirely new conception of the proper work of dispensaries. Instead of devoting most of their efforts to cure disease already established, which is, of course, their oldest and hitherto most im-

portant function, dispensaries should take a substantial part in preventive medicine by arranging conferences and medical examinations of persons who are not yet ill. In this way, they could undoubtedly detect a very large proportion of serious disorders in their incipency, or rather, they could detect symptoms which, if allowed to progress, would lead to serious disease. The Department of Health has taken this matter up with the Associated Out-Patient Clinics of New York, and it is hoped soon to be able to announce the definite establishment of this form of preventive work.

INCREASE OF PNEUMONIA IN NEW YORK.—Figures concerning last week's deaths in New York City, compiled by the Department of Health, show that during the week just passed, 1569 deaths occurred in the city, as compared with 1409 during the corresponding week of last year. The respective rates per 1000 population are 14.10 and 13.09. "This increase," said Registrar Guilfooy, "is due principally to the heavy mortality from pneumonia and the allied diseases and appears to be associated with the blizzard. Lobar pneumonia alone not only showed an immense increase in the mortality over the corresponding week of last year, but a very decided increase over that of last week."

There were approximately 1500 new cases of pneumonia in the city last week. The contagious diseases showed practically no increase in mortality during the past week, as compared with the corresponding week of 1914.

Examined from the viewpoint of age groupings, the mortality was highest in the middle and later periods of life. The mortality of children under five was lower than during the corresponding week of last year. The difference of 1.01 in the weekly rate is equivalent to an increase of 112 deaths. The death rate for the first fifty-one weeks of 1915 is 13.56, as compared with 13.66 for the corresponding period of last year.

SEIZURE OF KIDNEY CURES.—Action against several so-called "kidney cures" has recently been taken under the Food and Drugs Act by the United States Department of Agriculture. In one case the shippers of a preparation labeled as "A Sure Cure for Bladder and Kidney Trouble" were prosecuted on the charge of falsely and fraudulently misbranding the product. They pleaded guilty and were fined \$25 and costs by the court. This particular kidney "cure" was found to contain over 41% of alcohol. It was labeled "Old Jim Field's Phosphate Dill and Gin, Mankind's Greatest Friend, A Sure Cure For Bladder and Kidney Trouble. It is also a Great Aid in Case of Urinary Trouble. Allenberg & Meister, Sole Agents, Memphis, Tenn." An analysis of the product showed that it contained no material amount of either dill or phosphate.

In another case, 48 bottles of "Stuart's Buchu and Juniper Compound," prepared by the Stuart Manufacturing Company, Atlanta, Georgia, were seized. The court issued a decree of condemnation, forfeiture, and destruction on the ground that the claims upon the label were misleading, false, and fraudulent. On this label the manufacturers recommended their product as a remedy for a great variety of kidney and bladder diseases and stated that the medicine contained 16% of alcohol.

A MEMORIAL TO EUSTACHIUS.—In the issue of the *Lancet* for December 4 is contained the following account of a bronze memorial to Eustachius recently erected at the University of Bologna:

"Bartolommeo Eustachi, better known as Eustachius, was the sixteenth-century anatomist, who divides with his great rival Vesalius the post of honour as a pioneer in that *métier*. Born at San Severino in the Marches, he died in 1574 after a life-long tenure of the Chair of Anatomy in the Roman school, during which he impressed relays of pupils, Italian and foreign, as not only an inspiring exponent of the science, but as a devoted exemplar of the experimental or inductive method, and, on these lines, an enricher of its subject-matter. The monument, a *chef d'oeuvre* of the sculptor Giuseppe Tommini, represents the stately figure of Eustachius in academic robes, delivering from his chair a lecture to his students. In his left hand he holds a human cranium, while his right rests on the plates on which is engraved the intimate structure of the ear. On either side are grouped his young listeners in attitude of rapt attention. The ornamentation above consists of surgical instruments artistically disposed, and below the inscription, from the pen of Signor Giri, professor of Latin, runs as follows:—

Bartolomaeo Eustachio
Pienti
Artis Anatomicae Lumini
Senatus Academicus
Quartis Feriis Secularibus
Anno MDCCCCXIV.

"The unveiling was preceded by a brief discourse from the Rector Magnificens, Professor Tonelli, in presence of His Excellency the Prime Minister, Signor Salandra; the Minister of Public Instruction, Signor Grippo; the Syndic, Don Prospero Colonna; the Senatus Academicus; and an effective representation of the scientific, artistic, and literary bodies of Rome."

COMPARATIVE MORTALITY IN 1849.—In a report of the New Orleans Board of Health for 1849, are noted the following comparative death rates in four large American cities in that year: Boston 22 per thousand, New York 27, Charleston, S. C., 25, and New Orleans, La., 66.

AMERICAN FIRST AID CONFERENCE.—As the result of a resolution passed by the American First Aid Conference, President Wilson has appointed the following Board of Standardization, to a study of the problems of first aid, with a view to improving the methods and equipment and to standardize them for the various industries as far as possible. The Board will report the results of its investigations at the next meeting of the conference.

Chairman.—Dr. Richard H. Harte, of Philadelphia, Pa., representing the American Surgical Association.

Secretaries.—Assistant Surgeon-General W. C. Rucker, representing the Public Health Service; Dr. J. Shelton Horsley, of Richmond, Va., representing the American Medical Association; Dr. S. C. Plummer, of Chicago, Ill., representing the American Association of Railway Surgeons; Major Robert U. Patterson, representing the War Department and the American Red Cross; Surgeon A. M. Fauntleroy, representing the Navy Department; Col. Louis A. Lagarde, U.S.A. Retired, representing the War Department; and Dr. J. P. Kaster, Topeka, Kansas, representing the Association of Railway Chief Surgeons.

The following committees are among those already appointed to coöperate with the Board of Standardization. Each State Medical Society has been invited to follow suit.

The American Medical Association (Surgical Section).—Dr. F. B. Lund, of Boston, Mass.; Dr. S. F. Mitchell, of Washington, D. C.; Dr. J. M. Wainwright, of Scranton, Pa.

The American Surgical Association.—Dr. Edward Martin, of Philadelphia, Pa.; Dr. Emmet Rixford, of San Francisco, Cal.; Dr. J. B. Blake, of Boston.

The Southern States Association of Railroad Surgeons.—Dr. Southgate Leigh, of Norfolk, Va.; Dr. Bacon Saunders, of Ft. Worth, Texas; Dr. Ambrose McCoy, of Jackson, Tenn.

District of Columbia Medical Society.—Dr. Charles S. White, of Washington; Dr. Wm. P. Reeves, of Washington; Dr. H. H. Kerr, of Washington.

Conference Board of Physicians in Industrial Practice.—Dr. John J. Moorhead, of New York City; Dr. W. Irving Clark, of Worcester, Mass.; Magnus W. Alexander, of West Lynn, Mass.

ASIATIC CHOLERA IN THE PHILIPPINES.—Report from Washington, D. C., states that before the Philippine committee of the Senate, on December 17, 1915, a surgeon of the army medical corps stated that during the past year there were 10,000 deaths from Asiatic cholera in those islands, the majority of which were due to the inefficiency of the native Filipino health officials.

PREVALENCE OF MALARIA, PELLAGRA, SMALL-POX AND TYPHOID FEVER.—The weekly report of the United States Public Health Service for December 10, 1915, states that during the month of

October there were in Mississippi 21,654 cases of malaria, 888 of pellagra, 119 of smallpox and 718 of typhoid fever. During the same period there were in Arkansas 95 cases of pellagra and 153 of typhoid. There were 49 cases of malaria and 104 of typhoid fever in California, and in Kansas 218 cases of typhoid and 83 of smallpox.

LONDON DEATH RATES IN OCTOBER.—Statistics recently published show that the total death rate of London during October, 1915, was 14.6 per 1000 inhabitants living. Among the several districts and boroughs, the highest rate was 20.3 in Finsbury, a crowded central region, and the lowest was 9.8 in Wandsworth, a populous southern suburb.

EUROPEAN WAR NOTES.

CHICAGO WARD AT AMERICAN AMBULANCE.—Report from Chicago states that at a public meeting in that city on December 16 the sum of \$10,000 was raised by popular subscription to establish and maintain a Chicago ward in the American Ambulance Hospital at Neuilly, Paris.

CHOLERA IN AUSTRIA HUNGARY.—The weekly bulletin of the United States Public Health service for December 10, 1915, states that during the period of three weeks ended on September 11, there were reported in Austria 6761 cases of Asiatic cholera with 4117 deaths. During the fortnight ended October 3, there were in Hungary 561 cases with 333 deaths. A large majority of all these cases was among the civil population. Since October 2, the number of all cases has rapidly diminished. There have been only 743 cases in all Austria since that time.

WAR RELIEF FUNDS.—On Dec. 25, the totals of the principal New England relief funds for the European War reached the following amounts:

Belgian Fund	\$77,413.27
Serbian Fund	58,042.07
Allied Fund	44,562.80
French Fund	32,132.82
Armenian Fund	26,447.06
Surgical Dressings Fund ...	16,324.00
LaFayette Fund	13,958.99
Italian Fund	13,772.02
Polish Fund	11,701.08

BOSTON AND NEW ENGLAND.

THE WEEK'S DEATH-RATE IN BOSTON.—During the week ending December 25 there were 242 deaths reported, with a rate of 16.86 per 1000 of population, as compared with 207 and a rate of 14.66 for the corresponding week of last year. A notable difference was a total of 44 deaths from pneumonia against 26 last year.

There were 40 deaths under 1 year and 76 over 60 compared respectively with the totals 35 and 70 last year.

Deaths under 1 year reported in 51 weeks from Jan. 2 to Dec. 25 were 1967 against 1954 for the corresponding period in 1914.

During the week the number of cases of the

principal reportable diseases were: Diphtheria 49, scarlet fever 44, measles 51, typhoid fever 1, whooping cough 50, and tuberculosis 39. Included in the above were the following cases of non-residents: Diphtheria 10, scarlet fever 1 and tuberculosis 2.

Deaths from these diseases were: Diphtheria 4, scarlet fever 1, measles 2, whooping cough 4, and tuberculosis 18; and included in these were the following deaths of non-residents: Diphtheria 3, scarlet fever 1, and tuberculosis 1.

The total number of 1915 deaths reported to noon of Dec. 26 was 11,626 against 11,509 in the same period last year. For the balance of the year 1914 there were 322 deaths reported, making the 1914 total 11,831 and the death-rate 16.06 the lowest rate Boston ever had. If the number of deaths to complete this year's total be also 322 then the total for 1915 will be 11,948 and the death-rate 15.96,—a new low record.

FIRE IN THE MARINE HOSPITAL, CHELSEA.—A fire, which seriously alarmed patients in the Marine Hospital at Chelsea, occurred recently in a storage room of the building. The hospital was at no time in danger, but the smoke rose to the wards and 63 patients had to be moved to another part of the building in order that they might not be suffocated. The loss to the structure was not heavy, but some valuable furniture and curios belonging to Dr. Irwin, the former superintendent of the hospital, were damaged.

BOSTON VITAL STATISTICS IN NOVEMBER.—A recently published monthly bulletin of the Boston Health Department for November, 1915, contains a statement of the mortality rates of this city for that month and for the first eleven months of the year as compared with similar periods in the past.

"Figures for the first eleven months of the year indicate that the rate will be less than six per 100,000, which is probably lower than ever reached by New York, Chicago, Cleveland, Philadelphia, St. Louis, Pittsburgh or Baltimore. Boston's rate from 1906 to 1910 per 100,000 population was 16; from 1911 to 1913 it was 9.2. The figures for last year were 9.2.

"For the four weeks ending Nov. 27, Boston had 800 deaths from various causes reported, as against 848 in the corresponding period of last year. Deaths under one year in the forty-seven weeks from Jan. 2 to Nov. 27 were 1812, as against 1804 for the corresponding period of 1914. The number of deaths reported in the same period was 10,621, as compared with 10,645 for the corresponding forty-seven weeks of last year."

HOSPITAL BEQUESTS.—The will of the late Ellen Channing, of Boston, which was filed in the Norfolk probate court on Dec. 20, contains bequests of \$2000 to the Channing Home, Boston, and \$5000 to the Massachusetts General Hospital for the provision there of a free bed.

SCIENTIFIC MEETINGS IN NEW ENGLAND.—

During the current convocation week there have been held in New England several meetings of national scientific societies affiliated with the American Association for the Advancement of Science, which is holding its sessions at Columbus, Ohio. From December 28 to 30 the Association of American Anatomists met at New Haven, Conn., under the presidency of Prof. G. Carl Huber of the University of Michigan. In Boston, from December 27 to 30, were held the meetings of the American Physiological Society, under the presidency of Prof. Walter B. Cannon of the Harvard Medical School; the American Society of Biological Chemists, under the presidency of Professor Walter Jones of the Johns' Hopkins University; and the Society of Pharmacology and Experimental Therapeutics, under the presidency of Dr. Torald Sollman of Western Reserve Medical School.

WORK OF THE ADAMS NERVINE ASYLUM.—The recently published thirty-eighth annual report of the managers of the Adams Nervine Asylum, recording the statistics of patients treated in that institution during the past year, calls attention to the charity administered by its trustees, whose extent and purpose is perhaps little realized by physicians in Massachusetts.

This institution provides fifty beds for residents of Massachusetts, of both sexes, who are suffering from nervous troubles, who are not insane and who may reasonably expect to be benefited by residence in the institution. Alcohol and drug habits are not desired. Sufferers from chronic organic spinal disease are so unlikely to show improvement from a few months' stay there that they are not apt to be received. Patients suffering from hysteria, psychasthenia (or neurasthenia) are received and a large number are recovered or improved during a three or four months' residence.

The most common misapprehension (and a very natural one) regarding the scope of this institution, is that insane patients are received there, or that it is a place where a compromise may be made so that a patient needing restraint may avoid being sent to an insane hospital. This is an error, for under the terms of Mr. Adams' will no insane person may be treated there. In fact, it is the only institution in the state that receives nervous patients that is prohibited from caring for the insane.

In recent years 75% of the patients have been treated without payment, or at a rate much less than cost. The remainder pay moderate sanitarium prices. The institution is not a home, nor a convalescent hospital in which patients are received to recover from operations or illness. While there are thirteen beds for men, it often happens that there are not applicants enough to keep them occupied.

Miscellany.

INCREASING COST OF DRUGS.

In the issue of the JOURNAL for December 23, we again commented on the continuing rise in cost of a large number of standard drugs and preparations. During the past week this rise has continued, and the following report from New York on December 16 announces the highest rate on record for opium and other products.

"Notwithstanding an acknowledged decrease of 50% in the consumption of narcotics in the United States during 1915, owing to the restrictive influences of the federal Harrison Anti-Narcotic law, which went into effect March 1 last, prevailing prices for ordinary druggists' quality gum opium stand at \$11 per pound, the highest figure on record.

"The upward movement in opium has become particularly pronounced of late, and the extreme levels which have been attained are primarily due to the serious Balkan complications, which prevent all shipments of Macedonian gum at a time when this market is cut off from all supplies from Turkey, that country being able to ship its goods to Germany and countries in the Tenton alliance only.

"To complicate and intensify further the general feeling of uncertainty as to this drug, it has just become known that the Turkish crop will probably be not more than fifty per cent. of the 1914 yield, which amounted to 8000 cases. The indicated yield of not more than 4000 cases of medicinal opium from Turkey will be the smallest Turkish opium crop harvested since 1907, and crop statistics indicate that only in ten years out of the past half-century have smaller crops been gathered.

"At the opening of 1915, druggists' quality gum opium in case lots was obtainable in the New York market on the basis of \$9.00 per pound. A downward movement set in during March and April under inadequate absorption and heavy receipts from abroad, until a \$7.50 basis was reached for the gum, \$11.00 for the powdered and \$11.50 for the granular. The turn in the opium situation has been reached, however, and purchases of all sorts of narcotics by the belligerents in Europe have assumed enormous proportions.

"The underlying reasons for the present base of \$11.00 for medicinal gum opium is not hard to trace in view of the almost complete cessation of imports, owing to the siege of Constantinople and the shutting off of the Macedonian supplies.

"Realization on the part of all domestic handlers that the cutting off all supplies from abroad renders existing opium stocks impossible of replacement, keeps the various narcotics in a strong position, morphine sulphate being maintained at \$5.50 and \$5.80, morphine acetate at

\$7.15, morphine alkaloid at \$7.15, and morphine hydrochloride at \$5.00 and \$5.80, while codeine alkaloid is held at \$8.60 an ounce, codeine acetate, hydrochloride and nitrate at \$7.80, codeine phosphate and salicylate at \$6.55, and codeine sulphate and hydrobromide at \$6.95. Manufacturers of the above derivatives may again be forced to arbitrarily revise their quotations in order that they may bear their approximate proportion of cost to the newly established values of sulphate of morphine and codeine.

"According to statistics released by the Government, opium stocks in the United States are shrinking at the rate of \$90,000 and \$100,000 worth per month. The stock of opium containing 9 per cent. and over of morphia in our bonded warehouses on October 1, 1915, amounted to but 47,189 pounds of the value of \$205,680, comparing with 67,687 pounds of the value of \$293,658 on Sept. 1, 1915, and 92,997 pounds of the value of \$394,088 on October 1, 1914. The imports of opium containing 9% and over of morphia for the nine months ended Oct. 1, 1915, amounted to but 298,237 pounds of the value of \$1,436,816, which contrasted with 271,926 pounds of the value of \$1,210,274 in the corresponding nine months of 1914, and 532,575 pounds of the value of \$2,315,978 for the corresponding period in 1913. The great bulk of the gum, 262,328 pounds, was received from Turkey, only 27,253 pounds having been received from Great Britain and 8656 pounds from other countries during 1915.

Latest despatches received here from Salonica state that the prices of opium have increased considerably because the arrivals from the producing districts had been stopped for an indefinite time on account of the Bulgarians occupying the different centres of production and because such opium would now be considered the product of an enemy country. Practically all the producing centres of Macedonia have been ravaged by the Bulgarian invasion, and the sowing of seeds has not been made under normal conditions.

"Morphine and codeine, though in unabated demand from the belligerents, have not advanced commensurately with the rise in crude opium. Just how extensive this export movement in the narcotics is, it is difficult to ascertain in the absence of official statistics. The exports of crude opium to Europe in the first nine months of the 1915 calendar year, however, amounted to 34,357 pounds of the value of \$176,569, against practically none in previous years.

"Manufacturers of bromide preparations have just announced advances of 90 to 100 per cent. over and above their previous quotations, owing to the continued scarcity of potash. The newly established basis for granular bromide of potash is \$5.50 per pound, against a previous quotation of \$2.50 per pound, while for crystallized bromide of potash \$5.60 per pound is asked against

a previous quotation of \$2.60 per pound. The advances in other bromide preparations have amounted to from \$1 to \$2 per pound, the newly established price for strontium bromide being \$3.50 and \$3.52, against the previous quotation of \$2.50, while bromide of soda was advanced to \$4.50 against the previous figure of \$2.50, and bromide of ammonia was raised to \$4.50 per pound against the previous figure of \$3 per pound. Among the other potash compounds which have been subjected to advances within the past few days are permanganate, which has been raised to \$1.60 and \$1.75 per pound; U. S. P. bicarbonate of potash, which was advanced from 65 cents to 70 and 75 cents per pound; and sulphide of potash, which is 2 cents higher, at 35 and 37 cents per pound. So far as first hands in potash materials are concerned the most important development was the announcement of a 5 cents advance in the contract price for chlorate of potash, following which manufacturers withdrew from the market.

"Another of the interesting phases of the general situation as regards the exportation of explosive materials has been the greatly enhanced values being asked by crushers of castor beans. Announcement of another two cents flat advance has just been made, and quotations are now given as 14¾ cents per pound for standard grades in barrels, 15 cents for 'A A' and 16 cents for 'Crystal.' Aside from the demand for castor oil as a high-class lubricant for war purposes, the factors operating for the advance have been the great diminution in shipments of the raw materials, castor seed and castor nuts, from India. Private advices received here indicate that more than twenty-two vessels out of a total of thirty sailing from Indian ports have been requisitioned by the British government. Not only does this have a vital effect on the very backbone of the domestic production of the article, but taken in conjunction with the fact that English castor oil factors have been forced to operate their plants on something like fifty per cent. of a normal schedule, it is little wonder that prices reflect the abnormality of underlying conditions."

THE CONTROL OF DIPHTHERIA.

In the monthly bulletin of the Massachusetts State Department of Health for November, 1915, appears a leading article on the control of diphtheria, emphasizing the importance not only of prompt treatment of actual cases, but of the judicious immunization of susceptible individuals during times of epidemic. This article, after noting the fact that during the past year there have been in Massachusetts 639 deaths from diphtheria, continues as follows in descrip-

tion of the value of the Schick test in the determination of individual susceptibility to diphtheria infection:

"A new and useful aid has been put into our hands by the laboratory. It has come as the result of the studies of Professor Schick of Vienna. From a long series of experiments he has devised a simple and safe test, which shows whether a given individual is susceptible to diphtheria or not. This will be invaluable in many ways.

The results of its use are already apparent. We are now reasonably certain that 80% of the new-born, 50 to 60% of children, and 90% of the adults are naturally immune from diphtheria. This throws new light upon the spread of the disease and explains why only certain persons take diphtheria even when exposed to it. This test will show whether a person has sufficient antitoxin in his blood to overcome an infection with diphtheria bacilli.

Some of the other uses of the Schick test can be summarized as follows:

1. It will enable the practising physician to diagnose doubtful membranes of the throat.

2. It will enable us to separate the susceptible from the non-susceptible individuals who have been exposed to diphtheria.

3. It will enable us to administer antitoxin to those only who actually need it.

4. It will enable us to prevent the accidents due to serum sickness, for we can determine by the use of this test whether a larger amount of antitoxin serum would have any ill effects.

5. It will enable us to lessen the yearly expenditure for unnecessary antitoxin.

6. It will enable us, when diphtheria bacilli are demonstrated in the throat of an apparently well person, to determine whether this person is coming down with the disease or whether he is a "carrier."

It will be seen from these uses that the Schick test has the possibility of a wide range of usefulness."

In order to familiarize the profession and local health authorities with the nature of this test, Dr. Milton J. Rosenau, director of the antitoxin and vaccine laboratory of the State Department of Health, has prepared the following description of the Schick reaction, which is also published in the bulletin.

"The Schick reaction is a skin test used to determine whether the individual examined is immune or susceptible to diphtheria.

The Schick test is made by injecting a small amount of diphtheria toxin into the skin. The amount injected is one-fiftieth of a minimum lethal dose for a 250-gram guinea-pig. The injection must be made *into* and not *under* the skin. The toxin is diluted with salt solution so that the correct amount to be injected is contained in just 0.1 cubic centimeter. Use a good

1 cubic centimeter tuberculin syringe graduated in tenths and a fine platinum-iridium or steel needle. The operator should be skilled in the intra-cutaneous method of injecting.

If the blood of the individual tested contains diphtheria antitoxin there will be no reaction at the site of the injection, for the reason that the toxin is at once neutralized by the antitoxin. The absence of reaction, therefore, signifies the presence of antitoxin; such persons are immune to diphtheria; they may, however, become bacillus carriers. The presence of reaction indicates the absence of antitoxin; such persons are susceptible to diphtheria.

If the injection has been properly made, a small wheal-like elevation appears, which shows the distinct markings of the openings of the hair follicles. This distention persists for two or three minutes.

A *positive* reaction appears in from twenty-four to forty-eight hours, as a distinctly circumscribed area of redness and slight infiltration, which measures from 1 to 2.5 centimeters in diameter. The redness increases in intensity during the next three or four days, persists for another week, and on fading gradually gives place to a brownish pigmentation, which always shows superficial scaling. The true reaction is characteristic of the irritant action of toxin on tissue cells when there is no antitoxin to protect them. In the case of a negative reaction, which indicates an antitoxin immunity to diphtheria, the skin remains normal in appearance.

A *pseudo-reaction* is seen occasionally in older children and in adults. This is not due to the irritant action of toxin, but is an anaphylactic response of the skin to the protein substance of the diphtheria bacillus present in solution in the broth used in making the toxin. Such a reaction can also be obtained with a dilution of the autolysate of the diphtheria bacillus, in which no toxin is present. The pseudo-reaction can generally be distinguished clinically from the true reaction; it appears earlier, is less sharply circumscribed, and usually disappears in from three to four days. It is characterized by a central area of redness of varying size, surrounded by a secondary areola. On fading it leaves only a faintly pigmented area, which soon becomes invisible. It will be safer, for those insufficiently experienced, to regard pseudo-reactions as true reactions.

It is important that the toxin be kept cold (on the ice), and it should be used within seventy-two hours after the date of preparation, which is marked on the label.

Note.—The department is not yet prepared to send out the materials for the Schick test for general distribution. For the present, arrangements can be made for the application of the test through the state district health officer of any particular district."

WORK OF THE UNITED STATES PUBLIC HEALTH SERVICE.

THE recently published annual report of the Surgeon-General of the United States Public Health Service records the largest amount of work performed in the history of that organization. Since the passage of the law of 1912 the public health functions of the service have materially broadened, thereby increasing greatly its usefulness to the American people. Throughout the report the economic importance of disease prevention is made apparent to the reader.

Perhaps the most important achievement of the year was the discovery that pellagra is a deprivation disease, resulting from a faulty diet containing an excess of carbohydrates. While the final experiments which led to this discovery have only recently been completed, the conclusion itself is the culmination of investigations extending over a period of seven years. The work has consisted of epidemiological field studies, actual feeding experiments conducted at numerous places in Georgia and Mississippi, and experimental research at Spartanburg, South Carolina, and other places.

A new national quarantine station was opened at Galveston, Texas, and the control of the Boston station was transferred to the Public Health Service. A great reduction in immigration has been observed during the year, with a corresponding increase in the number of aliens certified. At the port of New York, the percentage has risen from 2.29, previous to the development of the European conflict, to 5.37 since that time; this increase largely being due to the fact that with the decreased immigration more time can be devoted to the examination. The number of cases treated at Marine Hospitals and relief stations exceeded 55,000, 15,000 of which were hospital patients, a considerable increase over previous years. The Coast Guard cutter *Androsoggin* was fitted out as a hospital ship and now affords relief to deep sea fishermen on the Banks of Newfoundland.

On the occurrence of plague at New Orleans, the first outbreak upon the Gulf seaboard, the state and local health authorities requested the Public Health Service to take charge of the situation. Extensive rat-proofing and other anti-plague measures were undertaken, resulting in the eradication of the disease from among human beings, and the practical extermination of the rodent infection.

Great reduction in the incidence of malaria was obtained in localities where surveys were conducted. Drainage projects, rice culture studies and the conditions surrounding the impounding of water for power purposes were investigated in order to eradicate as far as possible the disease in these areas. Scientific investigations of malarial infection showed that in the latitude of this country the most important agent in carrying the infection through the winter season

is man, and not the infected, hibernating, Anopheles mosquitoes, as was previously supposed. From the standpoint of prevention this is a discovery of considerable value.

Studies of occupational diseases and industrial hygiene were instituted at several places during the year. A survey of the industries of Cincinnati was made to determine the cause of the prevalence of tuberculosis among industrial workers. The investigations relating to the migration of persons suffering from tuberculosis were completed. Upon the request of the health authorities of five states, the organization and operations of the respective boards of health were studied and recommendations advanced for improvement in the powers and duties of these bodies. The health organizations of several cities were likewise investigated. Investigations of the pollution of streams and the examination of shellfish were also conducted.

Trachoma was combated in the Appalachian Mountains, where it is most prevalent, over 12,000 cases being treated. Surveys in certain states during the year showed that the disease is not an uncommon infection. Rural sanitation work was conducted in six different states, and everywhere resulted in the reduction of typhoid and other communicable diseases. Public health laboratories for the prevention of the interstate spread of disease were established at Chicago, Seattle, and numerous railway centers. Additional duties have been imposed upon the Service by extension of relief benefits to the newly organized Coast Guard and the physical examination of seamen applying for the rating of "able seaman." For this reason, and because of the greatly increased health functions of the Service, an increase in the commissioned personnel is recommended. An additional building for the Hygienic Laboratory and the establishment of a National Leprosarium for the proper segregation and care of cases of leprosy are also recommended.

Correspondence.

AN ENGLISH AUTHORITY ON EPISIOTOMY.

Boston, Dec. 24, 1915.

Mr. Editor: In yesterday's issue of the JOURNAL, you published an interesting article by Dr. Williams on episiotomy. This operation was also discussed and recommended by Dr. John Phillips in an article in the issue of the *Lancet* for November 27, 1915. Without expressing my own opinion about the advisability or indication for this procedure, may I call your attention to the following letter upon the subject which appeared in the issue of the *Lancet* for December 4. In this letter Dr. Spencer comments in part as follows on Dr. Phillips' article and upon episiotomy as an operation.

"I hope that your readers, before performing it, will note the many opinions which have been expressed against it. Dr. Phillips says: 'Parvin was one of the earliest advocates of the operation in America.' It seems to me that in the 1905 edition of

his 'Science and Art of Obstetrics' Parvin advocates it with faint praise. This is all he says about it in ordinary type:

"Episiotomy. If a serious tear of the perineum seems inevitable, many advise that an incision or incisions be made to prevent this accident. This practice, though generally credited to Michaelis, 1810, was recommended by Ould, 1742."

"In small type he goes on to say:

"Opinions differ as to the necessity for incisions, and also on the part of those who approve of the operation as to where they should be made. The late Dr. A. H. McClintock stated that he had so often seen the perineum escape laceration where this accident seemed inevitable, he was led to doubt the possibility of recognising the cases in which incision is an absolute necessity. . . . Tarnier states that the incisions do not always prevent even quite extensive tears, and they may leave deformity and a painful cicatrix, or the duct of one of the vulvo-vaginal glands may be divided and a fistula result. . . . He cautions against episiotomy unless it is quite indispensable, for he has sometimes seen the incised parts covered with eschars and become the medium of grave infectious accidents. Delore states that he accepts in extreme cases the slight operation, but in ordinary cases it is preferable to have a median rent which cicatrizes uniformly than two external ones which result in deformed cicatrices."

"Dr. Parvin quotes two authors only, Dr. Broomall and Dr. Manton (whose names as obstetrical authorities are unknown to me), as favoring the operation, but sums up the matter in these words:

"It may be stated that episiotomy will very seldom be plainly indicated, and in private practice will rarely be done."

"Dr. Munro Kerr says:

"It is an operation which is rarely required."

"Dr. Dakin says of episiotomy, whether unilateral or bilateral:

"This will possibly enable the head to pass the vulva more rapidly, but that is all that can be said for it. On the other hand, it is in the first place never certain that laceration will occur at all and the cuts may be useless and, what is more, afford an entrance to septic matter. In the second place, laceration may occur even when episiotomy has been done. In the third place, a tear made by the head, if properly sutured, heals most satisfactorily even when it extends into the rectum, and in these severe cases episiotomy would be useless. It is therefore not to be recommended under any circumstances unless a dense cicatricial condition of the perineum is found, when possibly some harm might be averted by a central incision carried as far as the sphincter if necessary."

"Having given a few of the adverse opinions of obstetricians of great experience, with whose views I entirely agree, I may add that episiotomy incisions sometimes extend and, dividing the fascia and levator ani, give rise to rectocele of the most intractable kind. I have such a case under my care at the present time."

"I am, Sir, yours faithfully,

"HERBERT R. SPENCER, M.D., Lond."

Dr. Spencer may surely be regarded as a distinguished English authority on obstetrics and gynecology and in consideration of the advocacy of episiotomy by Dr. Williams and Dr. Phillips, it seems fair that Dr. Spencer's expert opinion, and others which he cites, should also be considered.

Very truly yours,

"OBSTETRICUS,"

SCHOOL FOR HEALTH OFFICERS.

SPECIAL LECTURES IN JANUARY.

All lectures will be given from five to six o'clock on the dates specified and in the amphitheatre of Build-

ing E of the Harvard Medical School, unless otherwise indicated. All lectures will begin promptly on the hour.

January 4. "Oral Prophylaxis" (3 lectures). Dr. W. H. Potter, Professor of Operative Dentistry, Harvard Medical School.

January 6. "Infant Mortality" (3 lectures). Dr. John Lovett Morse, Associate Professor of Pediatrics, Harvard Medical School.

January 10. "Venereal Prophylaxis" (2 lectures). Dr. Hugh Cabot, Assistant Professor Genito-Urinary Surgery, Harvard Medical School.

January 11. "Oral Prophylaxis." Dr. W. H. Potter.

January 12. "Venereal Prophylaxis." Dr. Hugh Cabot.

January 13. "Sanitary Law" (6 lectures). Prof. Eugene Wambaugh, Professor of Law, Harvard Law School.

January 14. "School Hygiene" (2 lectures). Dr. T. F. Harrington, formerly Director of Hygiene, Boston Public Schools.

January 18. "Infant Mortality." Dr. John Lovett Morse.

January 19. "Oral Prophylaxis." Dr. W. H. Potter.

January 20. "Sanitary Law." Prof. Eugene Wambaugh.

January 21. "School Hygiene." Dr. T. F. Harrington.

January 24. "Maritime Quarantine" (2 lectures). Dr. S. B. Grubbs, U. S. Public Health Service.

January 25. "Infant Mortality." Dr. John Lovett Morse.

January 26. "Quarantine." Dr. S. B. Grubbs.

January 27. "Sanitary Law." Prof. Eugene Wambaugh.

January 28. "Industrial Hygiene." Dr. T. F. Harrington, Deputy Commissioner State Board of Labor and Industries.

HARVARD UNIVERSITY FREE PUBLIC LECTURES ON MEDICAL SUBJECTS.

The Faculty of Medicine of Harvard University offers a course of free public lectures, to be given at the Medical School, Longwood Avenue, Boston, on Sunday afternoons, beginning January 2, and ending May 7, 1916. The lectures will begin at four o'clock and the doors will be closed at five minutes past the hour. No tickets are required.

SUNDAY AFTERNOONS AT FOUR O'CLOCK.

Jan. 2. Dr. R. B. Greenough, "Cancer."

Jan. 9. Dr. W. H. Potter, "Military Dentistry; Experiences in a Three Months' Service in the American Ambulance Hospital, Paris."

Jan. 16. Dr. R. P. Strong, "Progress in Combating Epidemics of Some Infectious Diseases."

Jan. 23. Dr. R. B. Osgood, "Orthopedic Problems Presented by the European War."

Jan. 30. Dr. J. A. Honcij, "Leprosy."

Feb. 6. Dr. C. M. Smith, "Syphilis."

Feb. 13. Dr. F. H. Verhoeff, "Some Simple Facts Regarding the Eyes That Everyone Should Know."

Feb. 20. Dr. W. H. Robey, Jr., "The Value of Physical Examination to the Individual."

Feb. 27. Dr. C. J. White, "Occupation as a Contributing Factor to Certain Skin Diseases."

March 5. Dr. W. R. Bloor, "The Role of Fat in the Nutrition of Man."

March 12. Dr. F. S. Newell, "The Care of Pregnancy." (To women only.)

March 19. Dr. J. L. Goodale, "Hay Fever and Asthma."

March 26. Dr. F. W. White, "Chronic Indigestion."

April 2. Dr. J. R. Torbert, "A Comparison of the Methods for the Relief of Pain in Childbirth." (To women only.)

April 9. Dr. P. G. Stiles, "The Present Conception of an Adequate Diet."

- April 16. Dr. G. B. Magrath, "Death by Accident; Some of Its Causes and How to Eliminate Them."
- April 23. Dr. H. P. Mosher, "The Management of Foreign Bodies in the Trachea, Bronchi and Esophagus."
- April 30. Dr. C. V. Chapin, "What the Individual Can Do to Protect Himself from Infection."
- May 7. Dr. R. J. Lee, "The Importance of Physical Examination in Health as Shown by the Examination of Harvard Students."
- Copies of this announcement and further information in regard to any of the lectures may be obtained by addressing The Chairman of the Committee on Public Lectures, The Harvard Medical School, 240 Longwood Avenue, Boston, Mass.

NOTICE.

THE MASSACHUSETTS GENERAL HOSPITAL will open a consultation clinic for people of moderate means on Tuesday, January 25, 1916. Every Tuesday and Friday afternoon at 2 P.M. patients referred by their physicians will be received at the Out-Patient Department on Fruit Street for consultation and diagnosis only. These are hours apart from those of the regular Out-Patient clinic.

Physicians are requested, if possible, to accompany their patients. When a physician is unable to accompany his patient, he will be expected to send a letter referring him to the hospital. This letter will be answered and as far as possible the diagnosis given and treatment suggested.

The clinic is designed for the benefit of families with small incomes. Diagnosis has become so complex and expensive in obscure and difficult cases that its cost has become a heavy burden to those who, nevertheless, are able and willing to pay something. It is expected that physicians will not refer to it people of considerable means.

A fee of \$5.00 will be charged. When an x-ray examination is needed, a fee of \$2.00 to \$3.00 will be charged in addition. For certain other laboratory tests charges not to exceed \$1.00 will be made. The \$5.00 admission fee includes more than one visit when these are necessary for a diagnosis.

SOCIETY NOTICES.

ESSEX NORTH DISTRICT MEDICAL SOCIETY.—A Semi-Annual Meeting of the Essex North District Medical Society will be held in Centre Church vestries, corner of Main and Vestry Street, opposite City Hall, Haverhill, Mass., (Tel. 548), Wednesday, January 5, 1916, at 12 noon, sharp.

A paper will be presented upon "The Public Health Nurse as an Educative Factor," by Dr. A. N. Little, Newburyport. (15 minutes.)

The balance of the meeting is devoted to symposium of three papers upon the work of the first Harvard Unit abroad. (20 minutes each) as follows:

"Otolaryngeal, and Rhinological War Surgery," by Dr. H. P. Mosher, of Boston.

"General War Surgery," by Dr. H. F. Hartwell, of Boston.

"War Medicine," by Dr. F. W. Snow, of Newburyport.

V. A. REED, M.D., *President*.

J. FORREST BURNHAM, M.D., *Secretary*.

NEW ENGLAND PEDIATRIC SOCIETY.—The fortieth meeting of the New England Pediatric Society will be held in the Boston Medical Library, Friday, Jan. 7, 1916, at 8.15, P.M.

1. President's Address. A. C. Eastman, M.D., Springfield.

2. "Indigestion with Fermentation." J. I. Grover, M.D., Boston.

3. "The Problem of Ringworm in Children." E. Lawrence Oliver, M.D., Boston.

4. "Results of Open-Air Treatment in Pneumonia." A. R. Cunningham, M.D., Boston.

Light refreshments will be served after the meeting.

2. "Benjamin Waterhouse," Dr. A. K. Stone.

3. Exhibition of books and papers.

Medical students and physicians are cordially invited to attend.

ERNEST G. GREY, M.D., *Secretary*.

APPOINTMENTS.

NEW YORK HEALTH DEPARTMENT.—In order to carry on the large amount of administrative work heretofore performed by the Deputy Commissioner, Dr. John S. Billings, until now Director of the Bureau of Preventable Diseases, has been designated to act as Deputy Commissioner. His place as Director of the Bureau of Preventable Diseases has been taken by Dr. Bertram Waters, heretofore Chief, Division of Tuberculosis, in that Bureau. Dr. C. D. Martin will act as Chief of the Division of Tuberculosis. The changes are merely official designations by the Board of Health and carry with them absolutely no changes in salary or Civil Service titles.

BOSTON DISPENSARY.—Dr. Malcolm Storer has been appointed surgeon-in-chief of the gynecological department. The associate surgeons appointed are Dr. Edward I. Twombly, Dr. Robert L. DeNormandie, and Dr. Stephen Rushmore. Dr. A. K. Paine, Dr. John B. Swift and Dr. John T. Williams have been appointed assistant surgeons; and Dr. Raymond S. Titus and Dr. Foster S. Kellogg assistants to surgeons.

RECENT DEATHS.

DR. A. MORGAN VANCE, who died on December 9 at Louisville, Ky., was widely known in his community as an orthopedic surgeon. He was president of the Kentucky State Medical Association and a fellow of the American College of Surgeons. He was sixty-one years of age.
